Sim Pack (Ziegler et al., 2006), is a Java based library that aims at encompassing several classes of measures ranging from strategies to compare string to information theoretic approaches (e.g., Resnik, Lin). The *Similarity Library* as compare to SimPack is more focuses on similarity between ontology concepts since it provides ad-hoc indexes for WordNet, MeSH and the Gene Ontology. Moreover, it provides two search-engine based strategies and a strategy to compute similarity between sentences.

Concluding Remarks and Future Work

This paper described the *Similarity Library*, a Java based tool encompassing several similarity measures relying on different sources of knowledge. The library includes knowledge-based methods that usually exploit some ontology as source of knowledge in the

process of similarity estimation. Moreover, also some approaches exploiting search engine indexes are implemented. The library can be easily extended to include other similarity measures thanks to its modular architecture, which provides a set of simple interfaces to be implemented.

As compared to existing approaches, the Similarity Library has some nice features: i) It speeds up similarity computation by exploiting ad-hoc indexes maintaining ontological knowledge; ii) it includes both ontology and search-engine based approaches that can also be combined; iii) it encompasses different ontologies, ranging from generic one such as WordNet to domain specific such as the Gene Ontology. Finally, the library can be easily integrated in an piece of Java code and then it is easily portable.

As future work, there are two main extensions. The first is the integration of similarity approaches exploiting Wikipedia such as WikiRelate! (Ponzetto and Strube, 2007). Wikipedia has recently emerged as a viable source of knowledge to compute similarity since it provides a huge amount of unstructured knowledge, on the form of Wikipedia articles, and a categorization mechanism through which articles are arranged in a hierarchy. This integration will also enable to combine knowledge-based approaches, which can rely on knowledge manually encoded by experts, with knowledge defined by a community. The second is to include FrameNet, which provides an on-line lexical resource for English, based on frame semantics and supported by corpus evidence Ruppenhofer *et al.* (2005).

Introduction

Bioinformatics approaches have led to the introduction of different methodologies and tools for the analysis of different types of data related to proteins, ranging from primary, secondary and tertiary structures to interaction data (Cannataro *et al.*, 2010).

The same is not true of for functional knowledge. The reason is related to an objective representation and measurable properties of protein sequences and structures, whereas functional aspects have neither. Thus, to compare functional aspects they must be expressed in a common and objective form. One of the most advanced tools for encoding and representing functional knowledge in a formal way is the Gene Ontology (GO) (Shah and Rubin, 2006; Ashburner *et al.*, 2000). GO is divided in three ontologies, named Biological Process (BP), Molecular Function (MF) and Cellular Component (CC). Each ontology consists in a set of GO terms representing different biological processes, functions and cellular components within the cell. GO terms are connected to each other to form a hierarchical graph. Terms representing similar functions are close to each other within this graph.

Biological molecules are associated with GO terms that represent their functions, biological roles, and localization through a process also known as annotation process. The annotation process can be performed under the supervision of an expert or in a fully automated way. For this reason, every annotation is labeled with an Evidence Code (EC) that keeps track of the type of process used to produce the annotation itself.

All the annotations involving a set of proteins or genes are commonly called the annotation corpus, and usually, refer to the whole proteomes and genomes (i.e., the annotation corpus of yeast). The availability of well formalized functional data enabled the use of computational methods to analyze genes and proteins from the functional point of view. An interesting problem is how to express quantitatively the relationships between GO terms. In order to evaluate the similarity among terms belonging to the same ontology, a set of formal instruments called Semantic Similarity Measures (SSM) have been developed. A SSM takes in input two or more terms of the same ontology and produces as output a numeric value representing their similarity. Semantic similarity applied to the GO annotations of gene products provides a measure of their functional similarity. Consequently, the use of SSMs to analyze biological data is gaining a broad interest from researchers (Milano *et al.*, 2014, 2016). The semantic similarity has become a valuable tool for validating the results drawn from biomedical studies such as gene clustering, gene expression data analysis, prediction and validation of molecular interactions, and disease gene prioritization. Over the years several approaches are proposed to quantify the semantic similarity between terms or annotated entities in ontologies.

Background/Fundamentals

A SS measure is a formal instrument that ensures the quantification of the relatedness of two or more terms within an ontology. There are two different measure approaches: the measures that quantify the similarity among two terms, often known as pairwise measures, and the measures able to describe the relatedness of two sets of terms, yielding a global similarity of sets, referred to as groupwise measures.

The similarity measures have been extended to gene and gene products that are annotated with terms belonging to the ontology, allowing to draw conclusions on the relationship of two proteins relying on the similarity of GO terms.

SS measures can be classified according to the properties of GO terms and annotation corpora on which they are based, and the strategies and models on which they rely. A typical categorization groups the SS measures which are based on: Term Information Content (IC), Term Depth, a common ancestor, all common ancestors, Path Length and Vector Space Models (VSM).

The measures based on Term Depth and IC evaluate terms similarity on the basis of the specificity of the terms. One concept commonly used in these approaches is information content (IC), which gives a measure how specific and informative a term is.

More formally, given an annotation corpus, the IC of a term c is defined as:

$$IC(c) = -\log p(c)$$

where $p(c)$ is the fraction of gene products that are annotated with term c or its descendants in the annotation corpus.

Measures based on a common ancestor select a common ancestor of two terms according to its properties and then evaluates the semantic similarity on the basis of the distance between the terms and their common ancestor and the properties of the common ancestor. IC is used to select the proper ancestor, yielding to the development of methods based on the information content of common ancestor: for instance, the Maximum Informative Common Ancestor (MICA)-based approaches select the common ancestor of two terms t_1 and t_2 with highest IC:

$$MICA(t_1, t_2) = \operatorname{argmax}_i IC(t_i)$$

$t_i \in \text{ancestors}(t_1, t_2)$

Resnik's measure (Resnik, 1995) (*simRes*), one of the most popular SS measures, is an exponent of this category. The semantic similarity between two terms t_1 and t_2 is simply the IC of the MICA:

$$\text{sim}_{\text{Res}}(t_1, t_2) = \text{IC}(\text{MICA}(t_1, t_2))$$

Lin's measure (Lin, 1998), *simLin*, considers both the information content of the MICA and of the input terms:

$$\text{sim}_{\text{Lin}}(t_1, t_2) = \frac{\text{IC}(\text{MICA}(t_1, t_2))}{\text{IC}(t_1) + \text{IC}(t_2)}$$

In a similar way, Jiang and Conrath's measure (Jiang and Conrath, 1997), *simJC*, takes into account the MICA and the input terms:

$$\text{sim}_{\text{JC}}(t_1, t_2) = 1 - \text{IC}(t_1) + \text{IC}(t_2) - 2\text{XIC}(\text{MICA}(t_1, t_2))$$

Also *simGIC* (Pesquita *et al.*, 2009) is a measure based on IC, but instead of focusing on only the most informative common ancestor of a pair of terms, it considers all the common ancestors of two sets A and B of GO terms:

$$\text{sim}_{\text{GIC}}(A, B) = \frac{\sum_{t \in \{\text{GO}(A) \cap \text{GO}(B)\}} \text{IC}(t)}{\sum_{t \in \{\text{GO}(A) \cup \text{GO}(B)\}} \text{IC}(t)}$$

where $\text{GO}(X)$ is the set of terms within X and all their ancestors in the GO hierarchy.

The measures based on all common ancestors (Gentleman, 2005; Sheehan *et al.*, 2008; Yu *et al.*, 2007; Couto *et al.*, 2007; Wu *et al.*, 2006; Li *et al.*, 2010) collect all the ancestors of terms, and then evaluate the overlap between the two sets, sometimes using also other characteristics, for example, IC or edge distance to determine term similarity. The measures based on Path Length (Yu *et al.*, 2007; Al-Mubaid and Nagar, 2008; Wang *et al.*, 2007; Othman *et al.*, 2008; Pekar and Staab, 2002; Wu *et al.*, 2006; Wu and Palmer, 1994) consider the length of the path from terms to their common ancestor that can be lowest common ancestor (LCA) – or maximum common ancestor – MCA. The measures based on VSM (Popescu *et al.*, 2006; Chabalier *et al.*, 2007; Bodenreider *et al.*, 2005) evaluated the similarity by considering the distance among vectors that are defined using topological considerations (e.g., the cosine of the induced angle), as well as semantic considerations (e.g., IC-based). The vectors are composed by the annotations of proteins. The calculation of protein semantic similarity consists of the evaluation of the semantic similarity between all the terms annotating two proteins, and then combine them in some way. Several measures for calculating the functional similarity between gene products have been proposed, which can be divided into two categories: pairwise and groupwise approaches. Groupwise Term SS measures can be directly extended to measure protein similarity, simply considering as input the two sets of GO terms annotating the proteins. Instead, Pairwise Term SS measures evaluate the similarity of pairs of terms and therefore, are not directly applicable to genes and proteins. Consequently, it is necessary to define a strategy, called mixing strategy, that transforms all the pairwise term similarities into a single representative value. There are six mixing strategies reported in the literature:

- Average (avg) strategy that considers the average of all term pairwise similarities (Lord *et al.*, 2003);
- Maximum (max) strategy that is based on the maximum of all term pairwise similarities (Sevilla *et al.*, 2005);
- Best Match Average (BMA) that relies on the average of similarity between best-matching terms (Azuaje *et al.*, 2005);
- funSim strategy determines the protein semantic similarities in MF and BP ontologies using max, avg or BMA mixing strategies and then they are combined together in a non-linear way (Schlicker *et al.*, 2006);
- Information Theory-based Semantic Similarity strategy filters the best matching pairs on the basis of their similarities, then the average is calculated (Tao *et al.*, 2007);
- FuSSiMeG strategy similar to max strategy; and the maximum of all term pairwise similarities weighted by the ICs of the terms is selected (Couto *et al.*, 2007).

SS measures are substantially different from all the other classical measures such as sequence similarity because they use information regarding the functions and roles of proteins themselves. However, the comparison of gene product using semantic similarity requires a well-defined ontology and a complete and reliable annotation corpus.

Furthermore, the SS measures have been verified to be good predictors of protein–protein interactions (Ivanov *et al.*, 2011). The robustness and generality of the analysis are certified by the heterogeneity of data used in different assessment methods. As expected, the best results are obtained when using BP ontology, while CC ontology has proven to be not particularly suited for this task (Guo *et al.*, 2006).

Different works (Chen *et al.*, 2009) identified Resnik as one of the best semantic similarity measures (Guo *et al.*, 2006), especially when combined with the max mixing strategy (Xu *et al.*, 2008). This is not unexpected since max strategy favors protein pairs sharing even only a part of their functions and, as we reported previously, two proteins are likely to interact even when they only have in common some of their aspects.

Systems and/or Applications

The current scenario is characterized by the different tools that ensure the computation of many SS measures; however, there is none tool that implements all the SS measures or that is easily extendible. Considering the distribution, tools are mainly available as web servers, i.e., FuSSiMeG, ProteInOn, functional similarity matrix (FunSimMat), GOToolBox, G-SESAME or as packages for the R platform, csbl.go, GOSemSim, GOVis. However, FuSSiMeG, protein interactions and ontology (ProteInOn), FunSimMat, csbl.go and SemSim together cover almost all the similarity measures. In general, tools are based on GO and annotation corpora. Some tools, such as the web servers, include their own copy of annotation corpora and GO, offering user-friendly solutions. However, they rely on maintainers for updated data and generally do not offer many possibilities of customization or extension. On the contrary, other tools such as stand-alone R-packages, are generally more flexible and often easily extendable, but they require the intervention of expert users. Usually, they require the user to provide annotations and ontologies as input data in more or less common formats. While this enables the full control over data used and guarantees the possibility to use most-updated data, the preparation of input datasets may result in an error-prone waste of time.

Analysis and Assessment

In this section the web servers tools and R platform tools are described.

FuSSiMeG-Functional Semantic Similarity Measure Between Gene-Products

FuSSiMeG (Couto *et al.*, 2003) is a tool that measures the semantic similarity between all the GO terms and functional similarity of gene products by comparing the semantic similarity between the annotations of genes products provided by Gene Ontology Annotation (GOA).

Given a gene product from SwissProt/TrEMBL, a list of GO terms assigned to a gene product in GOA is defined as:

$$T(g) = \{t : (g, t) \text{GOA}\}$$

where GOA is a set of pairs consisting of gene products and GO terms assigned in the GOA database.

FuSSiMeG assumes that two gene products have a functional similarity when they are annotated with terms functionally similar. The measure of similarity between gene products is calculated from the maximum of the similarity among their terms. FuSSiMeG is defined as:

$$FuSSiMeG(g_1, g_2) = \max\{SSM(t_1, t_2) : t_1 T(g_1) \wedge t_2 T(g_2)\}$$

where g_1 e g_2 are two gene products.

FuSSiMeG assumes that two gene products have functional similarities when they are annotated with similar functional terms and when these terms have a significant information content. Then, the previous expression is redefined as:

$$FuSSiMeG(g_1, g_2) = \max\{SSM(t_1, t_2)XIC(t_1)XIC(t_2) : t_1 T(g_1) \wedge t_2 T(g_2)\}$$

To compute the semantic similarity of gene products or the terms GO, FuSSiMeG requires as input the pair of proteins or GO terms of interest; FuSSiMeG computes the semantic similarity by selecting one measure among Resnik, Lin, JiangConrath, ResnikGraSM, LinGraSM, JiangConrathGraSM. The output consists of: the similarity score in percent and a weighted similarity score. The weighted similarity considers the information content of each term that is proportional to how many times the term is annotated.

ProteInOn- Protein Interactions and Ontology

ProteInOn (Faria *et al.*, 2007) is an online tool for exploring and comparing proteins within the context of Gene Ontology. It implements several semantic similarity measures for calculating protein and term similarity, and combines information on protein-protein interactions and GO term assignment for protein characterization. The tool can be used to compute semantic similarity between proteins or GO terms, using one of the three measures implemented (Resnik's, Lin's and Jiang and Conrath's measures) with or without the GraSM approach. Furthermore, it introduces a preliminary weighting factor to improve the specificity of these measures for protein semantic similarity, addressing the issue of their displacement from the GO graph. It can also be used to find GO terms assigned to one or more proteins or GO terms representative of a set of proteins. A preliminary score is used to measure the representativeness of a term for a set of proteins, based on the number of proteins the term is annotated to and its probability of annotation. The ProteInOn database contains protein and GO terms and is structured according to a relational model, implemented in MySQL. The main entities are, therefore, protein and GO terms, and major reports are the protein-GO terms annotations, protein-protein interactions and GO term-GO term ancestry. The data corresponding to these entities and relationships are imported from four public databases: UniProt, for the data source of protein which includes the accession numbers, names, and sequences, GO, for GO term data and a GO term-GO term ancestor; GOA for the annotation; IntAct for protein-protein interactions. The ProteInOn interface consists of a web page divided into four stages: entry input, query

selection, query options and results. ProteinOn takes as input up to five proteins or GO terms. The query selection depends on the kind of input. For the GO term, there are two available queries: 'get information content' which returns a list with the accession number, name and information content of each of the terms entered and 'calculate term similarity' which is available for two or more terms only, and returns for each pairwise combination of the terms entered, the semantic similarity score between them. The queries for proteins are:

'Find assigned GO terms' which lists all GO terms directly assigned to each of the proteins entered, and the evidence code(s) for that assignment; 'find interacting proteins' which returns a list of all proteins known to interact with each of the proteins entered; 'calculate protein similarity' which is available for two or more proteins, and returns for each pairwise combination of the entered proteins a set of semantic similarity scores between them. Each query ensures to select number of options for further specificity. For example, the user can limit the queries to one of the three aspects of GO or he/she can decide to ignore the IEA annotation from the analysis. Furthermore there is the options that limits the results to proteins that interact with all of the proteins entered only or the options that lists the GO terms that better represent the set of proteins entered, according to the representativeness score. Then, for the similarity queries, the user can select one of the three semantic similarity measures available, i.e., Resnik's, Lin's, and Jiang and Conrath's. The results are presented in tables, in which the output of the selected queries and the Similarity scores in percentage are reported.

FunSimMat

FunSimMat is a database that provides several different semantic similarity measures for GO terms. It offers various precomputed functional similarity values for proteins contained in UniProtKB and for protein families in Pfam and SMART. FunSimMat also provides several semantic and functional similarity measures for each pair of proteins with the GO annotation from UniProtKB and offers different types of queries available through a web interface. The first query consists of the semantic all-against-all comparison of GO terms contained in an input list provided by the user by using four different measures, simRel, Lin, Resnik, e Jiang e Conrath. The second query regards the comparison of one query protein or protein family with a list of proteins or protein families, which can be compiled in different ways. The simplest one is to enter the corresponding accession numbers into the query form of the website. The third query option is the definition of a functional profile. A functional profile consists of a list of GO terms from the biological process, molecular function or cellular component. This functional profile is treated as an annotation class and it is compared to a list of proteins or protein families. The web front-end provides HTML forms for all of the different query options that FunSimMat offers. The results are displayed in a table and can be downloaded as a tab-delimited text file or printed.

GOToolBox

The web server GOToolBox (Martin *et al.*, 2004) provides a set of programs that allow a functional study of groups of genes based on GeneOntology. It consists of a set of methods and tools that process the GO annotations for any species. All ontology data and the GO terms associated to genes are gathered from GO Consortium web site. GOToolBox performs five main operations: the building of gene dataset, the selection, and testing of the ontology level (GODiet), statistical analysis of the terms associated with the sets of genes (GO-Stats), gene clustering based on GO (GO-Proxy) and the recovery of genes based on the similarity of GO annotations (GO-Family). The dataset creation consists of retrieving, for each individual gene of the dataset, all the corresponding GO terms and their parent terms using the Dataset creation program. The genomic frequency of each GO term associated with genes in the dataset is then calculated. GO-Diet is an optional tool useful to reduce the number of GO terms associated with a set of genes data, to facilitate the analysis of the results, in particular when the list the gene of input and/or the number of associated GO terms is large. GO-Stats tool permits the automatic ranking of all annotation terms, and the evaluation of the significance of their occurrences within the dataset obtained by computing the frequencies of terms within the dataset and by comparing with reference frequencies. GO-Proxy tool groups together functionally related genes on the basis of their GO terms. GO-Family aims at finding genes having shared GO terms with a user-entered gene, on the basis of a functional similarity calculation.

G-SESAME

The web tool G-SESAME (Du *et al.*, 2009) is composed of four tools which includes the tool for measuring the semantic similarities of two and multiple GO terms, the tool for the semantic comparison of two gene products from two different species, and multiple gene comparisons and clustering tools. The tool for measuring the semantic similarities of two GO terms computes the semantic similarity by using the Wang measures among GO terms or GO terms set provided. The tool for measuring the semantic similarities of two genes from two species compares the functional similarities of two genes. The tool for multiple genes comparison computes the gene functional similarity measurement by applying Jiang's, Lin's and Resnik's methods. The output consists of the similarities of genes and also the clustering results of these genes (Table 1).

Table 1 Overview of web tools and their related functions and available semantic similarity measures

<i>Tool</i>	<i>Functions</i>	<i>Measures</i>
FuSSiMeG	SS measures, statistical tests	Resnik, Lin, JiangConrath, GraSM
ProteinOn	SS measures, search for assigned GO Terms and annotated proteins, representative of GO Terms	Resnik, Lin, JiangConrath, simGIC, GraSM, simU
FunSimMat	SS measures, disease-related genes prioritization	simRel, Lin, Resnik, JiangConrath
GOToolBox	SS measures, clustering	Si, Sp, SCD
G-SESAME	SS measures, clustering	G-SESAME

GOSemSim

The GOSemSim (Yu, 2010) is a R package developed to compute semantic similarity among GO terms, sets of GO terms, gene products, and gene clusters, providing five methods, four of which are based on the IC (Resnik, Lin, Jiang and Corrado and Schlicker) and one on the graph (Wang). The package provides six functions of which goSim, mgoSim, Genesim, cluster Sim calculate the semantic similarity between GO terms, a term set GO, GO descriptions of gene products and GO descriptions of gene cluster, while mgeneSim and mclusterSim are designated to calculate the matrix of similarity scores of a set of genes and gene clusters. For all six functions, the analysis is restricted to one of the three ontologies, “BP”, “MF”, “CC”. The goSim function provides the semantic similarity score for a pair of GO terms. The output consists of value between 0 and 1. The mgoSim function generates a score of similarity between two lists of GO terms. The genesim function estimates the semantic similarity between two genes. The mgeneSim function calculates the pairwise similarity scores for a list of genes. The mgeneSim automatically removes genes that have no annotations. The clusterSim function was developed to calculate the similarity between two gene clusters. This function computes the pairwise similarity between the gene products from different clusters and then provides the average of all similarities as the similarity of two gene clusters. The mclusterSim function calculates the pairwise similarity of a set of gene clusters.

GOvis

The GOvis package (Heydebreck *et al.*, 2004) calculates the similarity between GO graphs or between Entrez identifiers gene on their induced GO graphs. The relations between different terms of GO within one of the three ontologies are represented by a directed acyclic graph. The leaves of the graph represent the most specific terms and the connections between two nodes represent the relationship between the less specific and more specialized. The graph induced is a graph that is obtained from a specific node to the root, considering the various parents. Given a set of genes, it is possible to derive from GOA the specific set of annotations for these genes and, therefore, the graph induced by each of them. Starting from two graphs induced, three operations, the union, intersection and complement can be performed. GOvis implements two methods based on the graph structure, namely simUI and simLP. Both methods take as codominio the 0–1 range (a higher value implies a higher level of similarity). SimUI computes the intersection of the induced graphs for two genes. SimLP considers the depth of the path from a specified term to the root. More the paths are overlapping, more the terms will be similar.

Csbl.go

Csbl.go (Ovaska, 2016) package computes similarities for arbitrary number of genes and supports the following measures: Czekanowski-Dice, Kappa, Resnik (with GraSM as an option), Jiang-Conrath (GraSM), Lin (GraSM), Relevance, Cosine and SimGIC. The MICA-based measures (Resnik, Lin, Jiang-Conrath, Relevance and GraSM enhancements) are implemented as a combination of R and C++ code. Similarity computation needs GO term probabilities for the reference gene set, for this reason csbl.go provides precomputed probability tables for Homo sapiens, Saccharomyces cerevisiae, Caenorhabditis elegans, Drosophila melanogaster, Mus musculus and Rattus norvegicus. The tables are computed based on all gene and protein annotations for the given organism found in the geneontology.org database. The package also has an option to use custom tables. The taxonomy ID of the organism is stored along with probability tables as metadata, which enables selection of a table by organism ID. The package also includes an option to compute GO term enrichment using Fisher's Exact Test (Al-Mubaid and Nagar, 2008) (Table 2).

Discussion

During the years, an important component of biomedical research have become the ontologies. The reason is related to the characteristics of ontologies to provide the formalism, and common terminology necessary for researchers to describe their results. This ensures to easily share the results and reused ones by both humans and computers. The main advantage of the use of ontologies is the comparison of concepts and entities annotated with those concepts by using of semantic similarity measure. SS measures, i.e., the quantification of the similarity of two or more terms belonging to the same ontology, is a well- established field.

Table 2 Overview of R packages and their related functions and available semantic similarity measures

<i>Tool</i>	<i>Functions</i>	<i>Measures</i>
csbl.go	SS measures, clustering based on SS	Resnik, Lin, JiangConrath, GRaSM, simRel, Kappa Statistics, Cosine, Weighted Jaccard, Czekanowski-Dice
GOSemSim	SS measures	Resnik, Lin, Jiang, simRel, G-SESAME
GOvis	SS measures	simLP, simUI

There are two main approaches for this comparison: pairwise, in which entities are represented as lists of concepts that are then compared individually; and groupwise, in which the annotation graphs of each entity are compared as a whole. Until now, most research efforts in this area have been conducted to the development of different tools that ensure the computation of SS measures. However, there is a lack of tools that implements all the SS measures or that is easily extendible. Future efforts will address to implementation of tools that enable the computation all the SS measures and that ensure to integrate the next generation of SS measures. Furthermore, the work will direct to design faster solutions for the calculation of semantic similarity measures.

Marianna Milano received the Laurea degree in biomedical engineering from the University Magna Græcia of Catanzaro, Italy, in 2011. She is a PhD student at the University Magna Græcia of Catanzaro. Her main research interests are on biological data analysis and semantic-based analysis of biological data. She is a member of IEEE Computer Society.

Functional Enrichment Analysis Methods

Pietro H Guzzi, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The development of high-throughput experimental techniques, such as microarrays or next-generation sequencing, allow the screening of large number of genes and or proteins. Bioinformatics analysis, made on the gene input list, enable the identification of a subset of products that exhibit an “interesting” pattern of behaviour. The last step of the bioinformatics analysis consists of the interpretation of results from a biological perspective helping researchers to group genes. Such process is often referred to as enrichment, or functional enrichment, and consists of the individuation of the functions of the input list of genes by using annotations, i.e. known functions of the genes stored into biological ontologies. Consequently many algorithms and tools have been proposed, referred to as functional enrichment tools (Huang *et al.*, 2009). The increase of the use of such algorithms is clearly shown by the trend of the increase of the citations on search engines considering both articles describing novel methods and articles describing the use of existing ones. In parallel the scientific community has developed methodologies for classifying existing methods and website for suggesting the use of the appropriate algorithms.

Here we follow the classification proposed in Huang *et al.* (2009), that propose three main classes for such algorithms on the basis of the schema used for analysing input data. All the algorithms are based on three main pillars: (i) a list of genes or proteins, (ii) a source of annotations (i.e., formal descriptions of the functions) based on a biological ontology, e.g., Gene Ontology (Ashburner *et al.*, 2000), (iii) a way for testing the relevance of the annotations in the input list using statistical or semantic-based methods (Guzzi *et al.*, 2012).

The first class, called Singular Enrichment Analysis (SEA), groups traditional algorithms that receives as input a list of user preselected genes or proteins, and than tests the enrichment of each annotation term extracted from an ontology one by one and in iterative way. The second class, Gene Set Enrichment Analysis (GSEA), is similar to SEA from which differ considering the strategy to calculate the relevance (statistical and biological) compared to SEA. The last class, Modular Enrichment Analysis (MEA), calculates the enrichment using network based algorithms (Roy and Guzzi, 2015).

SEA algorithms take as input a list of genes or gene products that have been produced by the user (e.g. differentially expressed genes). Then they iteratively test the enrichment of each annotation term for each gene and finally the select the enriched annotation terms that satisfy the P-value threshold. The P-value threshold measure that probability that genes of the input list have a given annotation term with respect to a random chance, measured against a null model. The strength of SEA algorithms is their simple approach and the efficiency (Huang *et al.*, 2009). However as noted by Huang *et al.* a weakness is that the annotation term that pass the enrichment threshold may be very large.

The GSEA tools have the same principle of SEA but they differ on the calculation of the enrichment P-values (Cannataro *et al.*, 2015). The main idea of GSEA is to select all the genes in an experiment (not only the user-selected), therefore they reduce possible artefacts due to the gene selection step. Then they use all the genes to calculate the enrichment score and genes are ranked. MEA use the enrichment calculation method of SEA and incorporates extra network discovery algorithms by considering the term-to-term relationships (Di Martino *et al.*, 2015).

Singular Enrichment Analysis Algorithms and Tools

Singular Enrichment has been the first strategy for enrichment analysis. All the algorithms that implements this strategy take the user's preselected genes, and then iteratively test the enrichment of each annotation term one-by-one in a linear mode. After this step, each annotation term is associated to an enrichment probability (enrichment P-value) and each term passing the P-value threshold is reported to the user. Results are usually reported in a tabular format.

The enrichment P-value calculation is performed by using well-known statistical methods such as including Chi-square, Fisher's exact test, Binomial probability and Hypergeometric distribution. Examples of SEA tools are GoMiner, Onto-Express, DAVID, and GOEAST (see Relevant Websites section). Main weakness of tools in this class is that the linear output of terms can be very large and interrelationships of relevant terms are not evidenced.

GSEA Algorithms and Tools

GSEA approach is similar to SEA, i.e., the analysis of each annotation term separately, and uses a distinct algorithm to calculate enrichment P-values. The rationale of GSEA is to takes into account all the genes of an experiments while SEA selected only a subset of user selected genes. This strategy reduces the arbitrary factors in the typical gene selection step. GSEA algorithms calculates a maximum enrichment score (MES) from the rank order of all gene members in the annotation category. Then enrichment P-values are calculated by matching the MES to randomly shuffled MES distributions. Examples of enrichment tools in

the GSEA class are ErmineJ, and FatiScan (see Relevant Websites section). A complete list may be found at <https://omictools.com/gene-set-analysis-category>.

MEA Algorithms and Tools

MEA inherits the basic enrichment calculation found in SEA and incorporates extra network discovery algorithms. In this way MEA approaches are able to discover term-to-term relationships. The key advantage of this approach is that the researcher can take advantage of term-term relationships. The rationale is that relationships takes into account the biological meaning of the set of terms for a study. Examples of MEA tools are Ontologizer, topGO, and GENECODIS (see Relevant Websites section). A complete list may be found at <https://omictools.com/onttool>.

Gene Prioritization Using Semantic Similarity

Erinija Pranckevičienė, Vilnius University, Vilnius, Lithuania

© 2019 Elsevier Inc. All rights reserved.

Introduction

The year 2003 marked the completion of the Human Genome Project, and along with it a new scientific frontier. What immediately followed was an explosion of new research, possibilities, and substantial challenges. Where exactly do we find ourselves after more than a decade?

We are realizing previously unthinkable practical applications. Given the speed of molecular profiling technologies, personal genomics based medicine is becoming increasingly accessible (Dudley and Karczewski, 2013). Personalized precision medicine already offers individualized approaches to treatments according to individual genetic makeups (Fernald *et al.*, 2011). Beyond general public healthcare, direct to consumer (DTC) companies can sequence personal genomes upon request (Angrist, 2016). Today, in almost every area of biology and medicine the central question becomes: which gene and molecular markers associate with, or explicitly cause observed traits/phenotypes, and how? As of this writing, different modalities of high-throughput molecular profiling technologies are used to collect data and tackle these research areas. Microarrays and RNA-sequencing are used to analyze expression of genes in changing conditions. Chromatin-immunoprecipitation followed by parallel next generation sequencing (ChIP-Seq) is used for chromatin analysis and gene regulation. Genome and exome sequencing are used to study variation in the genome. Single cell sequencing is used to understand processes simultaneously occurring in a cell. All these technologies also generate huge amounts of data that has to be processed to extract useful knowledge (Tiffin *et al.*, 2009; Hawkins *et al.*, 2010).

The true value of this data depends on our ability to make correct links between molecular entities and the information stored in databases and literature (DeIaIglesia *et al.*, 2013). An unprecedented amount of information has to be processed to elucidate smaller subsets of essential genes or genomic variants related to the phenotype or condition. Just as a brief example - a single microarray experiment on mice brains and genetic susceptibility to stress may produce hundreds of differentially expressed genes. However, only a small subset of genes will actually contribute to the increased stress sensitivity. Hence the challenge - in genetic diagnostics, many single nucleotide polymorphisms (SNPs) can be identified in patient's genome/exome, yet only few are ever related to the observed trait and have explanatory power when it comes to the symptoms (Eilbeck *et al.*, 2017).

Here we come to the particularly difficult point of the research and methodologies described below. Reviewing all potential candidates or following a wrong lead might be extremely time consuming and costly (Hassani-Pak and Rawlings, 2017; Moreau and Tranchevent, 2012). However, selecting a small subset of best candidate genes might be very challenging, because one needs to interpret many complex relationships between observed phenotypes and candidate genes. To aid our search for the best candidate genes related to our target traits and phenotypes, we can now leverage modern computational tools. What follows is a thorough description of one such powerful method. The hope is that by utilizing this methodology in gene prioritization and combining it with other state-of-the-art tools, modern researchers and bioinformaticians will be able to substantially reduce time and errors in genetic discovery.

The importance of computational gene prioritization is evidenced by dynamics of scientific publications. Web of Science database has over two hundred articles published since 2005 (accessed in September 2017) whose primary topic is computational gene prioritization and 30% of these articles were published starting 2014 showing increasing interest in this field.

Computational gene prioritization aims to identify the most promising gene candidates related to a phenotype of interest from a large list of genes. In this process the connections between genes and biological processes of interest are derived and the genes are ranked according to the strength of those connections. The top ranking genes are the suggested best candidates (Moreau and Tranchevent, 2012; Bomberg, 2013).

Fundamental features that characterize a gene prioritization algorithm are (i) how a phenotype is defined and (ii) how an algorithm identifies links between genes and phenotypes. The definition of a phenotype will determine rules by which the algorithm will mine available data resources to retrieve gene-phenotype links. In practice, researchers try to use as many resources as possible. Information types and databases used to guide gene prioritization consist of already known genotype-phenotype relationships and its supporting evidence, homology between different species, gene expression data, interactions between the molecular entities and functional annotations of genes and gene variants (Aerts *et al.*, 2006; Hassani-Pak and Rawlings, 2017). Research teams may not only use conventional genomic data to prioritize gene candidates, but also images of gene expression maps in tissues (McClelland and Yao, 2017).

Recently established Monarch Initiative started integrating data from a large number of diverse resources for human and model organisms to aid in disease mechanism discovery and diagnosis (Mungall *et al.*, 2017) and the Monarch Initiative website. It unites large research centers and organizations worldwide leveraging resources of International Mouse Phenotyping Consortium (IMPC), Mouse Genome Database (MGI), Online Mendelian Inheritance in Man (OMIM) and portal of rare diseases Orphanet to integrate data describing diseases, phenotypes, environmental factors, drugs, literature, research resources and other.

Algorithmic approaches to gene prioritization can be classified into several broad categories – those that query existing resources and try to establish a chain of evidence linking genes to phenotypes (Perez-Iratxeta *et al.*, 2002; Pranckeviciene, 2015) and those that are based on principle of “guilty by association” (Wang and Marcotte, 2010). The latter is a dominating approach in most popular gene prioritization tools such as ToppGene (Chen *et al.*, 2009) and Endeavour (Tranchevent *et al.*, 2016; Moreau and

Tranchevent, 2012). Using functional properties of genes known to be associated with a disease phenotype of interest called training genes, the candidate genes are ranked by comparing them to the training genes (Valentini *et al.*, 2014; Bomberg, 2013). The comparison is carried out in all domains describing gene functions by assessing similarity of sequences, molecular interactions, biological pathways, gene product protein family domains and functional annotations and then aggregating the evidence (Aerts *et al.*, 2006) to prioritize the candidates (Moreau and Tranchevent, 2012). Extensive review of gene prioritization tools is presented in another article of this compendium by Marianna Milano.

This chapter is about analysis of complex biomedical data and prioritization of causative genes using semantic similarity searches in large hierarchical databases. We will outline a detailed example how Semantic Similarity can be applied to measure functional closeness of phenotypes and genes. We will demonstrate that it can serve as a powerful instrument in comparing annotations and groups of annotations organized as a hierarchical taxonomy.

Ontology Represents Organized Knowledge

First definition of ontology in computer science was given by Tom Gruber as “explicit specification of conceptualization” (Gruber, 2009). In philosophy an ontology is a way to understand and describe world. In computational and information sciences it is an instrument that enables modeling of knowledge about some real or imagined domain. Ontology provides machine readable language and method to structure and semantically describe a knowledge domain independently from its computational implementation. It can be understood as a controlled vocabulary which defines and specifies concepts, entities, relationships between them and other information relevant in modeling of that knowledge domain (Gruber, 2009; Hoehndorf *et al.*, 2015). Curated biomedical ontology contains organized knowledge that was reviewed by human field specialists so that ontology terms and their relationships are well defined. Most of biomedical ontologies are available for download from OBO Foundry – Open repository of biomedical ontologies (Smith *et al.*, 2007) and OBO Foundry website.

Gene Ontology

The most important ontology in biomedical and molecular sciences is Gene Ontology (GO). In GO knowledge about functions, compartments and biological processes in which known genes of all researched organisms take part is organized into three domains: Molecular Function, Biological Process and Cellular Component. These three domains are structured as taxonomic graphs in which the general terms precede the more specific terms. Each term in the taxonomy is assigned a unique identifier (for example cell communication is GO:0007154) and it can have multiple parents. The root concepts Molecular Function, Biological Process and Cellular Component are at the top of the hierarchy (Ashburner *et al.*, 2000) and Gene Ontology website.

A major purpose of Gene Ontology is to organize functional molecular knowledge about genes so that each gene can be characterized by what it does through Gene Ontology annotations/terms. As new gene functions are discovered or previously known functions are revised the corresponding genes are assigned a new or revised annotation. Each gene has its GO annotations listed in National Center of Biotechnology Information (NCBI) Gene database, Ensembl and other major gene information databases.

The graph structure of GO allows comparisons of GO terms and GO-annotated gene products by Semantic Similarity. The closer the two terms are in the GO graph, the more similar meanings they have. Comparison of GO term meanings helps in predicting/identifying protein–protein interactions, suggesting candidate genes involved in diseases and evaluating the functional coherence of gene sets (Pesquita *et al.*, 2009; Couto and Pinto, 2013).

Human Phenotype Ontology

Human phenotype ontology (HPO) is central in medical genetics and genomics. It provides “comprehensive bioinformatic resource for analysis of human diseases and phenotypes and serves as a computational bridge between genome biology and clinical medicine” (Köhler *et al.*, 2017) and HPO website. HPO provides a standardized vocabulary of abnormalities observed in human diseases. Its terms stand for well defined anatomical and functional properties that are used by medical practitioners to describe syndromes and clinical phenotypes. For the first time Semantic Similarity was used on HPO terms practically to aid in differential diagnosis of genetic diseases (Köhler *et al.*, 2009). HPO is under constant maintenance and development and its terms are being integrated into major online resources for medical genetics such as Decipher (Firth *et al.*, 2009) and PhenoTips (Girdea *et al.*, 2013) to annotate human diseases and to describe clinical symptoms.

HPO became a part of Monarch initiative (Mungall *et al.*, 2017) directed at integration of heterogeneous molecular biology data resources to aid diagnostics of genetic disorders. Because of its significant overlap with Mammalian Phenotype Ontology, HPO enables comparison of phenotypes between model organisms of different species by estimating their Semantic Similarity (Robinson *et al.*, 2014; Smedley and Robinson, 2015). This is very important because knowledge of gene-phenotype relationships discovered and confirmed in model organisms can inform unresolved gene-phenotype relationship cases in humans (Oellrich *et al.*, 2012; Robinson and Webber, 2014; Haendel *et al.*, 2015).

Semantic Similarity

Semantics (originating from Greek) denotes a philosophical and linguistic study of meaning. Semantic Similarity (SS) measures likeness of meaning of two concepts. For example, “an ocean” and “a sea” are semantically similar since both mean a large

continuous body of salt water. Concepts of “pears” and “apples” are semantically similar because both are tree-grown fruits. Proximity between meanings of concepts can be estimated numerically. It is computed using mathematical formulas that define Semantic Similarity (Sánchez and Batet, 2011). Notable domains in which a Semantic Similarity has found useful applications are: Natural Language Processing (NLP), Knowledge Engineering (KE) and Bioinformatics (Harispe et al., 2015):

- In NLP Semantic Similarity is used to compare units of language (words, phrases, sentences). It is applied to word sense disambiguation, text summarization, building textual corpora, semantic annotation and designing question answering systems.
- KE focuses on building machine-understandable knowledge representations such as controlled vocabularies and ontologies. Semantics of concepts in ontologies is already encoded by making relationships between the concepts explicit. Semantic Similarity in KE domain mostly is used to integrate, link and align different ontologies.
- In Bioinformatics a majority of the data is already structured and organized into ontologies (GO, HPO and other) that are available from Bio Portal (Whetzel et al., 2011). Semantic Similarity here mostly is used to analyze functional similarity of genes or phenotypes, to aid interpretation of poorly characterized gene functions, to guide clinical diagnostics and to help drug design (Harispe et al., 2015; Sánchez and Batet, 2011).

Formal Definitions

A problem of Semantic Similarity estimation in taxonomic networks dates back to seventies. The similarity in meaning of two concepts used to be estimated by counting edges connecting the concepts in the taxonomy. It was based on assumption that concepts connected by shorter paths have also similar meanings. However, this is not entirely true.

Philip Resnik was first to propose a different simple measure of SS of two concepts based on information content (IC) (Resnik, 1995). It measured how much information two concepts share in a hierarchical taxonomy. His approach was based on the generality of the concept which is expressed as a probability of its occurrence. For example, a root concept of the taxonomy such as Biological Process (BP) in Gene Ontology has a probability of occurrence equal to 1, since all other concepts in BP ontology are subsumed by this concept and also are biological processes. Therefore, Biological Process does not convey any information and has zero information content. More specific concepts down the hierarchy become narrower in meaning and have gradually higher information content. The SS between two concepts then is defined as the information content of the most informative (closest) common ancestor (subsumer) of both concepts. In this case, the closeness in meaning originates from the structure of the knowledge graph and a length of a path connecting the concepts becomes secondary. Therefore, a structure of the taxonomy/hierarchical graph became central in numerical estimation of SS between terms (Resnik, 1999). Recent theoretical work postulates an equivalence between information-theoretic definitions of Semantic Similarity and definitions in set theory (Sánchez and Batet, 2011).

Mathematical Definition

Given an ontology organized as a taxonomic graph its terms are used to annotate entities in some domain. For example, genes are annotated by the terms of Gene Ontology and human diseases are annotated by the terms of Human Phenotype Ontology. The purpose of annotation is to characterize entities in the domain. Some terms in the ontology are more specific and some are more general. Suppose that the terms in ontology O annotate entities in the domain D . Information Content (IC) of the term suggested by (Resnik, 1995) measures how specific and informative the i -th ontology term $_i$ is in its domain:

$$IC(\text{term}_i) = -\log(p(\text{term}_i)) \quad (1)$$

The $p(\text{term}_i)$ in Eq. (1) is a probability (relative frequency) of occurrence of the term $_i$ from the ontology O in the domain D . Information content of the terms in the ontology is always relative to the domain entities of which they annotate. Consider genes of some organism. Each gene is annotated by GO terms of Molecular Function, Biological Process and Cellular Component. The GO terms are organized hierarchically meaning that if a gene is annotated by the term $_i$, then it is also annotated by all ancestors of that GO term $_i$ and has all functional properties that the ancestor annotations designate. The probability of the term's occurrence is measured by a ratio of a number of genes the term and its descendants annotate over a number of all annotated genes in the domain:

$$p(\text{term}_i) = (\text{genes_annotated_by_the_term}_i \text{ and_its_descendants}) / (\text{all_annotated_genes_in_the_domain}) \quad (2)$$

Since every gene is annotated by the root term Biological Process and by all descendants of the root term, then the probability of occurrence of the Biological Process term in the Gene Ontology equals to 1 because every gene is involved in some Biological Process. Therefore, the Information Content of Biological Process annotation is 0.

The hierarchical structure of ontology makes possible a computation of Semantic Similarity. Usually, the annotations that have related meanings are also in close proximity in the hierarchical taxonomy. The most general concepts are at the top of the hierarchy. As we go from the top to the bottom the terms become more and more specific. Resnik suggested to measure SS between the ontology terms u and v as:

$$\text{Sim}_{\text{Resnik}}(u, v) = IC(\text{MICA}_{u,v}) \quad (3)$$

MICA abbreviates Most Informative Common Ancestor. Resnik's measure does not take into account the IC of the estimated concepts. Lin, Jiang and Conrath, Pirro and Euzénat and Mazandu and Mulder refined Resnik's measure to incorporate the IC of measured concepts. These modifications are reviewed in depth by (Harispe et al., 2014; Mazandu et al., 2016). More on SS

measures can be found in another article of this compendium “Tools for semantic analysis based on semantic similarity”. Out of many measures of Semantic Similarity the one that is used in all practical applications is Lin’s measure (Lin, 1998). It takes into account Information Content of both: the terms and their MICA:

$$\text{Sim}_{\text{Lin}}(u, v) = 2 * \text{IC}(\text{MICA}_{u,v}) / (\text{IC}(u) + \text{IC}(v)) \quad (4)$$

Measures of Semantic Similarity and their biomedical applications are extensively surveyed in work of Couto and Pinto, (2013); Sánchez and Batet, (2011); Sánchez *et al.*, (2012); Mazandu *et al.*, (2016); Pesquita *et al.*, (2009); Pesquita, (2017).

Computation in Ontologies

Semantic Similarity can be computed between the two terms in the ontology as well as between the annotated entities of the domain. Köhler *et al.* (2009) explains in depth how a principle of Semantic Search in Ontologies can be applied to differentiate diagnosis between Noonan Syndrome and Optic Syndrome using observed phenotypic abnormalities of Hypertelorism and Downward slanting palpebral fissures in an individual. In the following we compute explicitly and apply Information Content (Eq. 1) and Semantic Similarity (Eqs. 3 and 4) to compare syndromes defined by terms of Human Phenotype Ontology and to compare their associated genes annotated by Gene Ontology terms.

Semantic Similarity in HPO

The HPO curated terms currently annotate 1,0204 OMIM and ORPHANET diseases (HPO Website accessed December 2017). An example of a graph relating concepts in HPO is presented in Fig. 1. Left panel A in Fig. 1. shows a hierarchical structure relating a root term Phenotypic abnormality with the Abnormality of cerebral artery.

The terms become more and more specific going from the top to the bottom of the hierarchy. Each term represents some abnormality that may be encountered in some disease. The phenotypic abnormality specific terms are assigned to the diseases in which that abnormality may be manifesting. Therefore, each term in HPO annotates some number of the diseases. The root – Phenotypic abnormality – is assigned to all diseases currently annotated by HPO terms. Information Content of each term reflects its specificity and can be computed using Eq. 1. In order to compute Information Content of a term we need to know how many diseases are annotated by this term. A frequency of the HPO term means a proportion of diseases it annotates among all annotated diseases. Outline of computation of Information Content for five terms shown in Fig. 1 is presented in Table 1.

The terms *Abnormality of the vasculature* (HP:0002597) and *Abnormality of brain morphology* (HP:0012443) have broader meanings and are super classes for other terms. Therefore, they are annotated to more diseases than their descendants. This fact is reflected also in a lower IC of these terms compared to their descendant subclass terms.

Diseases in HPO are annotated with both: specific terms and their super class terms. For example, the term *Interrupted aortic arch* is a phenotype annotated to OMIM:616920 disease *Heart and brain malformation syndrome*. Another phenotype *Abnormality of the vasculature* is also annotated to the same OMIM:616920 disease just because it is a superclass of the *Interrupted aortic arch* phenotype. Similarly, the phenotype *Abnormality of brain morphology* is annotated to OMIM:616875 disease *Cerebral atrophy, visual impairment and psychomotor retardation* because this phenotype is a superclass of *Cerebral atrophy* that occasionally manifests in this OMIM:616875 disease (Source Monarch Initiative website). Superclass term is descriptive but usually it has a broader meaning.

Symptoms and syndromes organized into HPO ontology offer a framework to differentiate between competing diagnosis. The ontology enables to ask and answer questions such as: if a patient has *Abnormality of cerebral artery* (HP:0009145) and other symptoms that can be described by HPO terms, then which syndrome offers a best explanation of the observed symptoms? To find the matching syndrome, HPO terms of the patient’s phenotype are compared to HPO terms annotated to all diseases. A syndrome/disease that has highest Semantic Similarity to the patient’s phenotypic terms is suggested as a most viable.

We will use the *Abnormality of cerebral artery* to prioritize between the two diseases - *Heart and brain malformation syndrome* and *Cerebral atrophy, visual impairment and psychomotor retardation*. We will compare this *Abnormality of cerebral artery* phenotype with the HPO terms that are annotated to the mentioned diseases (shown in HPO graph in Fig. 1).

Semantic Similarity between the two terms in ontology is measured by Information Content of their most informative common ancestor (MICA) as defined in Eqs. (3) and (4). To start differentiating between the diseases we first find MICA of $u = \text{Abnormality of cerebral artery}$ and $v = \text{Abnormality of the vasculature}$. The terms u and v are connected by the two paths in Fig. 1. One path passes through the *Abnormality of the systemic arterial tree*. Another path goes through the *Abnormality of the cerebral vasculature*. Both these terms are closest common ancestors for u and v . However, we seek the most informative common ancestor and it would be the term with the highest Information Content. Calculations presented in Table 1 show that the term *Abnormality of the cerebral vasculature* has higher IC=3.87 than the IC=3.17 of *Abnormality of the systemic arterial tree*. Therefore, the most informative common ancestor is *Abnormality of the cerebral vasculature*. Through this ancestor only the patient’s phenotype *Abnormality of cerebral artery* connects with the term *Abnormality of brain morphology* that is a syndrome that is manifesting in and annotated to the disease *Cerebral atrophy, visual impairment and psychomotor retardation*. And through this ancestor only the same patient’s phenotype connects with another syndrome of *Abnormality of vasculature* that manifests in and is annotated to the other disease *Heart and brain malformation syndrome*.

Assuming that this is all that we know and applying Eq. (3) we compute Information Content of the most informative common ancestor $\text{IC}(\text{Abnormality of the cerebral vasculature}) = 3.87$ that is Resnik’s Semantic Similarity. From it alone we can’t decide whether the *Abnormality of cerebral artery* is closer in meaning to the *Abnormality of the vasculature* or to the *Abnormality of brain morphology* because its IC is the same 3.87 for both cases. However, using Lin’s Semantic Similarity defined by Eq. (4) we can

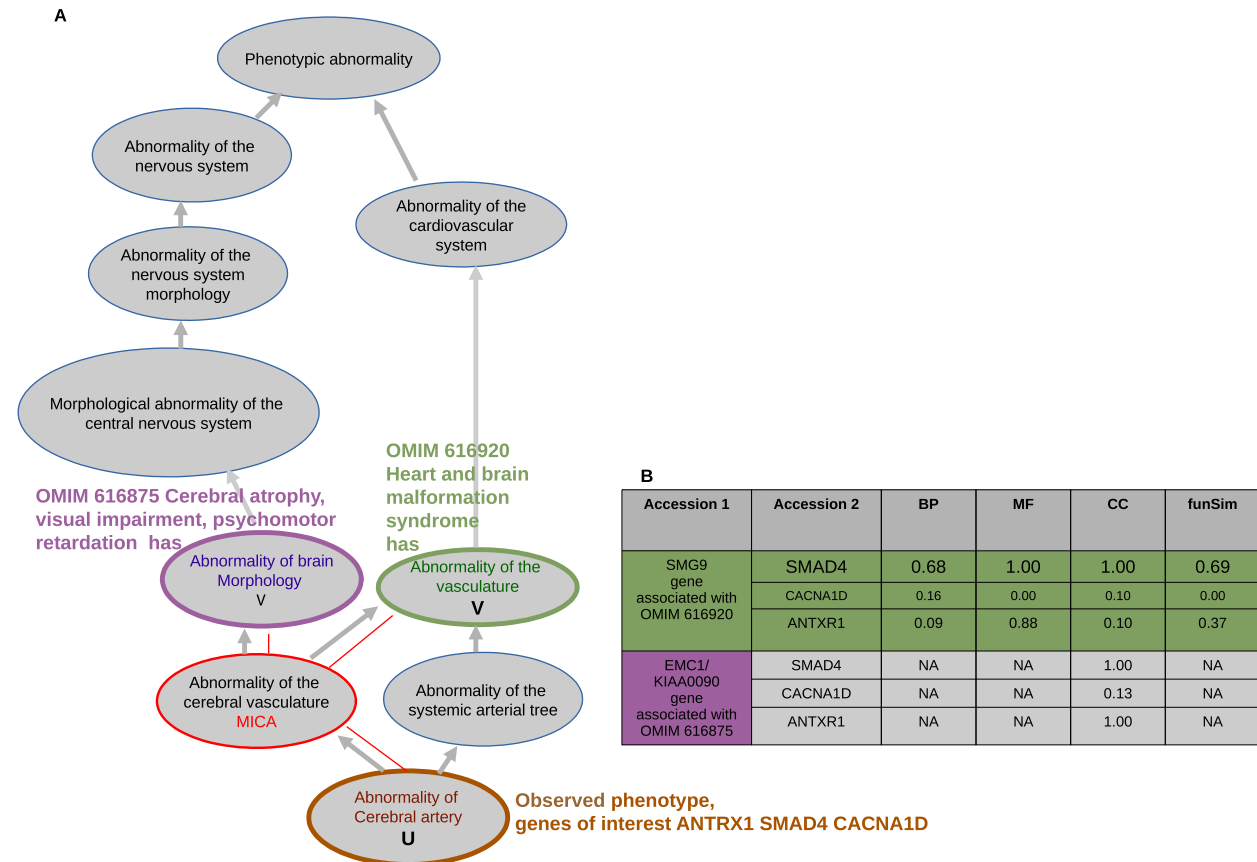

Fig. 1 Hierarchy of relationships between Human Phenotype Ontology terms and SS between genes. (A) Graph shows semantic relationships between the observed phenotype Abnormality of cerebral artery (U) and its ancestors. Among them, the Abnormality of brain morphology (V) is associated with OMIM disease Cerebral atrophy, visual impairment and psychomotor retardation which has an identified causative gene EMC1 (alternative name KIAA0090). The ancestor Abnormality of the vasculature (V) is a symptom observed in OMIM disease Heart and brain malformation syndrome. Its associated gene is SMG9. The observed phenotype U is linked to the phenotypes manifesting in diseases through the Abnormality of cerebral vasculature that is the Most Informative Common Ancestor (MICA) for the linked terms V, V and U. The observed phenotype is hypothesized to be associated with ANTRX1, SMAD4 and CACNA1D genes which we want to prioritize with respect to OMIM diseases. (B) Table shows Lin's SS estimates. Columns represent similarity between gene annotations of Biological Process (BP), Molecular Function (MF) and Cellular Component (CC) and the funSim column is an aggregated similarity score. Since EMC1 gene is poorly annotated it can't be meaningfully compared with other genes. It is represented by NA cells of similarity values between genes.

Table 1 Human Phenotype Ontology terms and their computed Information Content

HPO identifier	HPO term	# annotated diseases	IC = $-\log(\# \text{ annotated diseases}/n)$
HP:0009145	Abnormality of cerebral artery	72	4.95
HP:0100659	Abnormality of the cerebral vasculature	212	3.87
HP:0011004	Abnormality of the systemic arterial tree	429	3.17
HP:0002597	Abnormality of the vasculature	1578	1.87
HP:0012443	Abnormality of brain morphology	2956	1.24

Source: Total number of diseases annotated by HPO terms is $n=1,0204$ (last accessed September 2017).

take into account the informativeness of u and v :

$$\begin{aligned} \text{Sim}_{\text{Lin}}(u = \text{Abnormality of cerebral artery}, v = \text{Abnormality of the vasculature}) \\ = 2 * \text{IC}(\text{MICA}_{u,v}) / (\text{IC}(u) + \text{IC}(v)) = 2 * 3.87 / (4.95 + 1.87) = 1.13. \end{aligned}$$

$$\begin{aligned} \text{Sim}_{\text{Lin}}(u = \text{Abnormality of cerebral artery}, v = \text{Abnormality of brain morphology}) \\ = 2 * \text{IC}(\text{MICA}_{u,v}) / (\text{IC}(u) + \text{IC}(v)) = 2 * 3.87 / (4.95 + 1.24) = 1.25. \end{aligned}$$

With Lin's measure we are able to differentiate between these two terms. Based on a current knowledge existing in HPO, the *Abnormality of cerebral artery* is semantically closer to the *Abnormality of brain morphology* and therefore, the observed phenotypic evidence is better explained by the *Cerebral atrophy, visual impairment and psychomotor retardation* disease. We arrived at this conclusion using estimates of Semantic Similarity given that all that is known is *the phenotype observed in the individual that is Abnormality of cerebral artery*. In practice the phenotypes of the individuals are described by more HPO terms. The same reasoning and computation of Sim_{Lin} is applied to all pairs of HPO terms: where the pair contains the HPO term describing patient's phenotype and a term annotated to a disease. Then individual Sim_{Lin} estimates between the pairs of the terms computed for each disease are averaged for that disease (Köhler *et al.*, 2009). The disease characterized by a maximum average Sim_{Lin} would be suggested as the one which explains the observed symptoms best, based on the current knowledge that is present in the ontology.

Semantic Similarity in GO

Gene Ontology annotations describe functional properties of genes and biological processes in which genes are involved. Semantic Similarity can measure functional closeness of Gene Ontology (GO) annotations and functional similarity of annotated gene products. In most applications similarity between gene products is measured aiming to prioritize disease causing genes. Major sources of known associations between genes and diseases are the Online Mendelian Information about Man (OMIM) and the database of rare diseases ORPHAnet both of which document genetic diseases and their causes. Phenotypes in HPO have associated genes based on evidence in OMIM and ORPHAnet. For example, the *Abnormality of the cerebral vasculature* (Fig. 1) is associated with 552 genes. The SMAD4 and CACNA1D are among those genes and will serve as an example here. SMAD4 also is associated with the *Abnormality of the systemic arterial morphology* phenotype together with other 972 genes. Descriptions of these genes are shown in Table 2 (Monarch Initiative and Gene Ontology websites accessed 2018 February).

The SMAD4 and CACNA1D genes are associated with vascular phenotypes but not only. Gene ontology annotations of these genes show that they are related to the function and development of heart. These GO annotations are summarized in Table 3. Other GO annotations of these genes can be reviewed in Gene Ontology, Quick GO or NCBI Gene or UniProt websites.

Using previously described approach we can compute functional similarity between individual GO annotations of genes and their products. To aid this computation we use online FunSimMat tool (Schlicker *et al.*, 2010). Results of comparison of functional similarity between the selected GO terms from the Table 3 employing Lin's measure are shown in Table 4.

Two terms closest in meaning by $Sim_{Lin}=0.77$ are the *Regulation of atrial cardiac muscle cell membrane repolarization* and the *Cardiac conduction*. Semantic Similarity value computation relies on the knowledge encoded in the ontology (Table 4 Row 1) and

Table 2 Characteristics of genes associated with HPO phenotypes

Gene	Name	Total number of GO annotations	Entrez ID	UniProtKB ID	Number of associated phenotypes
SMAD4	SMAD family member 4	119	4089	Q13485	209
CACNA1D	Calcium voltage-gated channel subunit alpha1 D	36	776	Q01668	36

Table 3 Selected biological process annotations of CACNA1D and SMAD4 genes

Gene association with phenotype	Annotation	GO identifier	Annotated gene products
SMAD4 <i>Abnormality of the systemic arterial tree</i>	Positive regulation in cell proliferation involved in heart valve morphogenesis	GO:0003251	30
	Any process that increases the rate, frequency or extent of cell proliferation that contributes to the shaping of a heart valve		
	Cardiac septum development	GO:0003279	2663
	The progression of a cardiac septum over time, from its initial formation to the mature structure		
CACNA1D <i>Abnormality of the cerebral vasculature</i>	Brainstem development	GO:0003360	101
	The progression of the brainstem from its formation to the mature structure. The brainstem is the part of the brain that connects the brain with the spinal cord		
	Lipoprotein particle mediated signalling	GO:0055095	87
	A series of molecular signals mediated by the detection of a lipoprotein particle		
	Regulation of atrial cardiac muscle cell membrane repolarization	GO:0060372	127
	Any process that modulates the establishment or extent of a membrane potential in the polarizing direction towards the resting potential in an atrial cardiomyocyte		
	Cardiac conduction	GO:0061337	4264
	Transfer of an organized electrical impulse across the heart to coordinate the contraction of cardiac muscles. The process begins with generation of an action potential (in the sinoatrial node (SA) in humans) and ends with a change in the rate, frequency, or extent of the contraction of the heart muscles		

Table 4 Lin's Semantic Similarity between of selected GO annotations

Row	GO term 1	GO term 2	Lin SS
1	GO:0060372 Regulation of atrial cardiac muscle cell membrane repolarization (CACNA1D)	GO:0061337 Cardiac conduction (CACNA1D)	0.77
2	GO:0003279 Cardiac septum development (SMAD4)	GO:0003360 Brainstem development (SMAD4)	0.38
3	GO:0003279 Cardiac septum development (SMAD4)	GO:0061337 Cardiac conduction (CACNA1D)	0.36
4	GO:0003251 Positive regulation in cell proliferation involved in heart valve morphogenesis (SMAD4)	GO:0061337 Cardiac conduction (CACNA1D)	0.34
5	GO:0003251 Positive regulation in cell proliferation involved in heart valve morphogenesis (SMAD4)	GO:0060372 Regulation of atrial cardiac muscle cell membrane repolarization (CACNA1D)	0.31

this value fairly reflects that knowledge. We would expect the terms GO:0060372 *Regulation of atrial cardiac muscle cell membrane repolarization* and GO:0061337 *Cardiac conduction* to be semantically close since cardiac conduction involves membrane repolarization. Indeed, we see that these terms are closer semantically than the terms GO:0060372 *Regulation of atrial cardiac muscle cell membrane repolarization* and GO:0003251 *Positive regulation in cell proliferation involved in heart valve morphogenesis* (Table 4 Row 5). In the latter instance the two processes are biologically remote because morphogenesis belongs to development but regulation of membrane repolarization is characteristic to the continuous functioning of the heart. These terms are also far from each other in the GO hierarchy where their common ancestor GO:0050789 *Regulation of Biological Processes* is located almost at the root of the ontology. Since Gene Ontology has very complex structure of relationships between annotations, we refer interested reader to the Gene Ontology website Tools section AmiGo2. We recommend to use 'Visualization Creator' to obtain a visualization of hierarchical representation of relationships between a given subset of GO terms.

In gene prioritization by semantic similarities the annotations of different genes are compared to each other in pair wise manner. The maximum values of estimated semantic similarities are averaged resulting in a single similarity value for two genes/gene products that are compared (Schlicker et al., 2010). If a subset of genes is compared to a single gene, then the genes in the subset are ranked by a magnitude of the estimated similarity value. Top ranking genes will be most similar functionally to the gene with which they are compared. The actual measure of SS can vary. Most tools that are available have Resnik's, Lin's and Yang's measures of Semantic Similarity.

Lets assume a hypothetical situation that we observed a phenotype of *Abnormality of cerebral artery* and candidate genes SMAD1 (UniProt accession Q13485), CACNA1D(Q01668) and ANTXR1(Q9H6X2). We are interested in how similar these genes are to the causative disease genes - what is the extent of their functional similarity to the known causative disease genes for: OMIM:616920 disease *Heart and brain malformation syndrome* (associated gene SMG9 UniProt accession Q9H0W8) and OMIM:616875 disease *Cerebral atrophy, visual impairment and psychomotor retardation* (associated gene EMC1 gene UniProt accession Q8N766). To perform prioritization we use FunSimMat tool again that computes also semantic similarities between GO annotations of gene products given their UniProtKB accessions.

Results of prioritization are summarized on the right panel B in Fig. 1. Two Accessions columns show the compared genes. The BP, MF and CC columns show Lin's SS values in Biological Process, Molecular Function and Cellular Component classes. The funSim column is an aggregated overall similarity score (Schlicker et al., 2010). For the SMG9 gene known to be associated with the *Heart and brain malformation syndrome* the most functionally similar gene in the list of candidates is SMAD4. We note that this example is used only to demonstrate application of Semantic Similarity. A simplistic gene prioritization exercise serves only as a guide to illustrate computations. Though a relationship between the SMAD4 gene and the *Heart and brain malformation syndrome* may exist, its proof would require thorough analysis which is beyond of the scope of this reference work. As for the other case the causative EMC1 gene (whose alternative name is KIAA0090) does not have annotations for Biological Process and Molecular Function. Therefore, no meaningful comparison can be performed. Note, that EMC1 was identified as the causative gene in the exome sequencing assay (OMIM #616875). The EMC1 gene is an example of a less investigated and annotated gene at a time of writing. However, its annotation status will likely change in future. These examples demonstrate that Semantic Similarity search in ontologies is most powerful in well annotated and documented application domains.

Conclusion and Prospects

Gene prioritization field is actively researched and developed (Valentini et al., 2014). First ideas and papers on inferring links between genes and phenotypes in gene prioritization were published by Dr. P. Bork group early starting 1996. A notable example of the development in this field is Genes to Diseases system G2D (Perez-Iratxeta et al., 2002) to prioritize genes in inherited diseases. G2D system used knowledge in literature and RefSeq database as evidence to infer strongest links between genes and diseases. It used Semantic Similarity as an additional option to prioritize genes.

Another important system discussed widely in literature is gene prioritization tool Endeavour developed by Prof. Y. Moreau group (Tranchevent *et al.*, 2016). This system is based on “guilty by association” paradigm and requires training genes to define a functional characteristics of a phenotype of interest. Semantic Similarity is used to compare GO annotations as one channel of evidence. Other evidence comes from interactions, pathway, protein domain data and similarity scores are aggregated known as genomic data fusion algorithm (Aerts *et al.*, 2006).

Some systems were developed and supported no longer. Worth of mentioning are specific and broader systems that withstood challenges of time: Genie (Fontaine *et al.*, 2011), ToppGene (Chen *et al.*, 2009) and systems that utilize rich framework of R statistical computing environment (<https://www.r-project.org/>) (Cannataro *et al.*, 2015). Interested reader is also referred to the extensive review of gene prioritization tools in another article of this compendium.

Increasing use of next generation sequencing exome/genome data in clinical diagnostics is raising interest in tools of prioritization of genes and genomic variants (Eilbeck *et al.*, 2017; Yang *et al.*, 2015; Smedley and Robinson, 2015; Smedley *et al.*, 2015). Recently the phenotypic descriptions of symptoms in human diseases are becoming better formalized, organized and maintained as ontologies (Köhler *et al.*, 2017; Hoehndorf *et al.*, 2015; Girdea *et al.*, 2013). This makes easier to apply computational algorithms to gene prioritization (Masino *et al.*, 2014). Some genes in human are poorly annotated. However, this is not necessarily a case in model organisms (Haendel *et al.*, 2015). Semantic Similarity can be applied cross-species to translate known gene-phenotype relationships in model organisms to human organism and help to explain difficult cases (Oellrich *et al.*, 2012; Robinson *et al.*, 2014; Robinson and Webber, 2014). Application of Semantic Similarity to facilitate a use of biological knowledge cross-species proved to be very successful and underlies development of information resources for medical genetics in particular in Monarch initiative (Mungall *et al.*, 2017).

Gene Prioritization Tools

Marianna Milano, University of Catanzaro, Catanzaro, Italy

Introduction

The experiment platforms, such as mass spectrometry and microarray, usually produce a set of candidate genes potentially involved in different diseases (Cannataro *et al.*, 2013, 2010). Consequently, different approaches for selecting and filtering the genes have been introduced. These approaches are particularly used in clinical scenarios when the researchers are interested in the behavior of few molecules related to some specific disease.

Such approaches are known as gene prioritization methods. Gene prioritization aims at identifying the most promising candidate genes from a large list of candidates with respect to a biological process of interest, through the use of computational methods (Moreau and Tranchevent, 2012). Gene prioritization involves the following steps: the selection of a list of genes from the omics experiment, e.g. microarray or NGS; the gathering information about a disease from literature or from existing knowledge bases e.g. biological ontologies or repositories; the selection of a prioritization method; the production of a list of ranked genes. The Fig. 1. summarizes the Gene prioritization process.

In the past few years, many gene prioritization methods have been proposed, some of which have been implemented into publicly available tools that users can freely access and use.

These existing gene prioritization approaches can be classify according to the kind of input data, the used knowledge bases, and the selected prioritization methods. A fundamental step in gene prioritization consists of the integration of heterogeneous data sources related to biological knowledge.

Data sources are at the core of the gene prioritization problem since the quality of the predictions directly correlates with the quality of the data used to make these predictions. There exist different data sources such as protein-protein interactions, functional annotations, pathways, expression, sequence, phenotype, conservation, regulation, disease probabilities and chemical components. About functional annotations, reliable ontologies may be used as computer readable source of knowledge. Important examples of ontologies that may help the prioritization process are Gene Ontology (GO) (Gene Ontology Consortium, 2004), Human Phenotype Ontology (HPO) (Robinson *et al.*, 2008), and Disease Ontology (DO) (Schriml *et al.*, 2012). They offer both the organization of concepts through taxonomies and the association of a concept to gene products through annotations.

Generally, existing gene prioritization methods use ontologies only in a post-processing step after mining of textual data sources, e.g. the web. Moreover, different tools often use Gene Ontology, and one tool offers the possibility to use more than one ontology (Moreau and Tranchevent, 2012). Consequently, the need for the introduction of software tools able to help researchers to filter these lists on the basis of biological or clinical considerations (e.g. which molecules are more related to a given disease) arises.

Background/Fundamentals

This section recall background information on ontologies and semantic similarity related to gene prioritization process. Different prioritization tools use several ontologies during the prioritization by evaluating the similarity among the annotations of each

Fig. 1 Workflow prioritization process.

gene or gene product and of a selected disease. This is done by the use of semantic similarities (Guzzi *et al.*, 2012; Milano *et al.*, 2014). Semantic similarities are formal instruments to quantify the similarity of concepts in a semantic space. In the field of prioritization, semantic similarities are applied to quantify the similarity of a gene to a disease using the annotations of both elements on the same ontology.

Ontologies

Gene ontology

Gene Ontology (GO) is one of the main resources of biological information since it provides a specific definition of protein functions. GO is a structured and controlled vocabulary of terms, called GO terms. GO is subdivided into three non-overlapping ontologies: Molecular Function (MF), Biological Process (BP) and Cellular Component (CC). The structure of GO is a Directed Acyclic Graph (DAG), where the terms are the nodes and the relations among terms are the edges. The structure allows for more flexibility than a hierarchy since each term can have multiple relationships to broader parent terms and more specific child terms (du Plessis *et al.*, 2011). Genes or proteins are connected with GO terms through annotations by using a procedure also known as annotation process. Each annotation in the GO has a source and a database entry attributed to it. The source can be a literature reference, a database reference or computational evidence. Each biological molecule is associated with the most specific set of terms that describe its functionality. Then, if a biological molecule is associated with a term, it will connect to all the parents of that term (du Plessis *et al.*, 2011).

Human phenotype ontology

The Human Phenotype Ontology (HPO) is a standardized, controlled vocabulary that contains phenotypic information about genes or product genes. The HPO contains over 12,000 terms describing phenotypic features. The ontology is organized as three independent ontologies that include different categories: the mode of inheritance, the onset, and clinical course and the largest category of phenotypic abnormalities. The HPO is structured into a directed acyclic graph (DAG) in which the terms represent subclasses of their parent term and each term in the HPO describes a distinct phenotypic abnormality. About 110,301 annotations to HPO terms for almost 8000 diseases listed in the OMIM (Online Mendelian Inheritance in Man) database are also available at the website (see Relevant Website section). Diseases are annotated with terms of the HPO, meaning that HPO terms are used to describe all the signs, symptoms, and other phenotypic manifestations that characterize the disease in question. Since HPO contains information related to phenotypic abnormalities, the computation of semantic similarities among concepts annotated with HPO terms may enable database searches for clinical diagnostics or computational analysis of gene expression patterns associated with human diseases.

Disease ontology

The Disease Ontology (DO) database (see Relevant Website section) is a knowledge base related to human diseases. The current version stores information about 8000 diseases. The aim of DO is to connect biological data (e.g. genes) considering a disease-centred point of view. The DO semantically integrates a disease and existing medical vocabularies. DO terms and their DOIDs have been utilized to annotate disease concepts in several major biomedical resources. The DO is organized into eight main nodes to represent cellular proliferation, mental health, anatomical entity, infectious agent, metabolism and genetic diseases along with medical disorders and syndromes anchored by traceable, stable identifiers (DOIDs). Genes may be annotated with terms coming from DO that may be freely downloaded from the website. DO is structured into a directed acyclic graph (DAG), and the terms are linked by relationships in a hierarchy organized by interrelated subtypes. DO has become a disease knowledge resource for the further exploration of biomedical data, including measuring disease similarity based on functional associations between genes, and it is a disease data source for the building of biomedical databases.

Semantic Similarities

A semantic similarity measure (SSMs) is a formal instrument to quantify the similarity of two or more terms of the same ontology. Measures comparing only two terms are often referred to as pairwise semantic measures, while measures which compare two sets of term yielding a global similarity among sets, are referred to as groupwise measures. Since proteins and genes are associated with a set of terms coming from Gene Ontology, SSMs are often extended to proteins and genes. The similarity of proteins is then translated into the determination of similarity of a set of associated terms (Pesquita *et al.*, 2009; Wang *et al.*, 2010). Many similarity measures have been proposed (see for instance Guzzi *et al.* (2012) for a complete review) that may be categorized according to different strategies used for evaluating similarity.

For instance, many measures are based on information content (IC) of ontology terms. The information content of a term T of an ontology O is defined as $\log(p(c))$ where $p(c)$ is the number of concepts that are annotated with T and its descendants, divided by the number of all concepts that are annotated with a term of the same ontology. Measures based on a common ancestor first select a common ancestor of two terms according to its properties, and then evaluate the semantic similarity on the basis of the distance between the terms and their common ancestor and the properties of the common ancestor. IC can be used to select the proper ancestor, yielding to the development of mixed methods. The Resnik's similarity measure, sim_{res} , of two terms T_1 and T_2 of

GO is based on the determination of the information content (IC) of the their most informative common ancestor (MICA), where MICA is the common ancestor with the highest IC (Resnik, 1995):

$$sim_{Res} = IC(MICA(T_1, T_2))$$

A drawback of the Resnik's measure is that it considers mainly the common ancestor, and it does not take into account the distance among the compared terms and the shared ancestor. Lin's measure (Lin, 1998), sim_{Lin} , faces with this problem by considering both terms and yielding to the following formula:

$$sim_{Lin} = \frac{IC(MICA(T_1, T_2))}{IC(T_1) + IC(T_2)}$$

Jiang and Conrath's measure, sim_{JC} , takes into account this distance by calculating the following formula:

$$sim_{JC} = 1 - IC(T_1) + IC(T_2) - 2 \times IC(MICA(T_1, T_2))$$

Completely different from previous approaches, are the techniques based on path length (edge distance). In this case, similarity measures are correlated to the length of the path connecting two terms. Finally, many integrative approaches of two different categories have recently been proposed to achieve higher accuracy in measuring functional similarity of proteins. For example, Wang *et al.* (2010) proposed a combination of the normalized common term-based method and the path-length-based method. Their semantic similarity measure scores a protein pair by the common GO terms having the annotations of the proteins, but gives different weights to the common GO terms according to their depth.

Pesquita *et al.* (2008) proposed sim_{GIC} that integrates the normalized common-term-based method with information contents. Instead of counting the common terms, sim_{GIC} sums the information contents of the common terms.

$$sim_{GIC}(T_1, T_2) = \frac{\sum_{T_i \in C(T_1) \cap C(T_2)} \log P(T_i)}{\sum_{T_j \in C(T_1) \cap C(T_2)} \log P(T_j)}$$

where $C(T_1)$ is a set of all ancestor terms of T_1 . Finally, two recent IC based measures were proposed by Cho *et al.* (2013). The rationale is to integrate two orthogonal features. Since Resnik's method computes the information content of SCA (where SCA is the most specific common ancestor term) of two GO terms T_1 and T_2 , it focuses on their commonality, not the difference between them. In contrast, Lin's and Jiang's methods measure their difference only. sim_{ICNP} (information content of SCA normalized by path-length of two terms) uses the information content of common ancestors normalized by the shortest path length between T_1 and T_2 as the distance.

$$sim_{ICNP} = \frac{-\log P(T_0)}{len(T_1, T_2) + 1}$$

where T_0 is SCA of T_1 and T_2 . This method gives a penalty to Resnik's semantic similarity if T_1 and T_2 are located farther from their SCA. sim_{ICND} (information content of SCA normalized by difference of two terms' information contents) employs the information content of SCA normalized by the difference of information contents from the two terms to SCA, as Jiang's method does.

$$sim_{ICND} = \frac{-\log P(T_0)}{-\log P(T_0) - \log P(T_1) - \log P(T_2) + 1}$$

This method gives a penalty to Resnik's semantic similarity if the information contents of T_1 and T_2 are higher than the information content of their SCA.

Systems and/or Applications

The whole process of prioritization consists of different steps:

1. The first step consists of an omics experiment that produces a list of candidate genes identified through different technologies such as genomic microarray, expression microarray, next generation sequencing, micro-RNA microarray. The list can be filtered by using computational techniques, such as evidencing differentially expressed genes or potential mutations different in case/control studies.
2. The second step involves the collection of prior knowledge about the disease. Prior knowledge may be represented as keywords extracted from the literature using text-mining tools or as key- words selected by experts e.g. biologists or medical doctors. Analogously prior knowledge may be gathered from ontologies that represent a standardization of knowledge sources.
3. The third step consists of selecting the appropriate prioritization methods. The correct choice is crucial to obtain the best results.
4. The fourth step consists in the statistical evaluation of obtained results. After the validation ontologies may be used as a post-processing tool to evaluate the biological significance or the enrichment of selected candidate genes.

Analysis and Assessment

There exist many available approaches for gene prioritization that offer different functionalities to the community. Informations about these tools are summarized in The Gene Prioritization Portal (see Relevant Website section) (Börmigen *et al.*, 2012) that currently describes 46 tools that ensure the calculation of gene list prioritization.

This web site has been designed to help researchers to carefully select the tools that best correspond to their needs.

In general, the tools can differ in term of the inputs they require and the outputs they provide. There exist two types of inputs, the first one is the prior knowledge about the genetic disorder of interest. The prior knowledge regards the retrieval of a training set about at least, one disease causing gene or a complete set of keywords that covers most aspects of the disease.

The second type of input is the candidate search space, that consists of locus, or a differentially expressed genes (DEG) list, or the whole genome.

Regarding the outputs, two types were considered: a ranking of the candidate genes such that the most promising candidate can be found at the top and selection of the candidate genes that consists of a subset of the original candidate set, containing only the most promising candidates.

The first tool represents in The Gene Prioritization Portal is aGeneApart.

aGeneApart (Van Vooren *et al.*, 2007) takes as input a list of functional annotations from a variety of controlled vocabularies, including disease, dysmorphology, anatomy, development and Gene Ontology and creates as output a prioritized list of candidates.

BioGraph (Liekens *et al.*, 2011) allows prioritization of putative disease genes, supported by functional annotations from Gene Ontology.

Biomine (Eronen and Toivonen, 2012) integrates data from several publicly available biological databases on genes and phenotypes and returns a selection of candidates.

BITOLA (Hristovski *et al.*, 2005) mines MEDLINE database to discover new relations between biomedical concepts and returns a prioritized list of candidates and selection of candidates.

CANDID (Hutz *et al.*, 2008) uses several heterogeneous data sources, some of them chosen to overcome bias and returns a prioritized list of candidates.

CGI (Ma *et al.*, 2007) is a method for prioritizing genes associated with a phenotype by Combining Gene expression and protein Interaction data (CGI).

DIR (Chen *et al.*, 2011) is a tool based on an expandable framework for gene prioritization that can integrate multiple heterogeneous data sources by taking advantage of a unified graphic representation.

The DomainRBF (Zhang *et al.*, 2011) tool ensures the prioritization of genes and gene products associated with specific diseases. The user may select a disease phenotype and the prioritization is performed with Bayesian regression with respect to proteins contained in the Pfam database (Aerts *et al.*, 2009).

Endeavour (Aerts *et al.*, 2009) is a software application for the computational prioritization of candidate genes in multiple species. The process requires a training set of genes and it is based on functional annotations, protein-protein interactions, regulatory information, expression data. Endeavour can be used both as a web server and as a Java application.

G2D (Teber *et al.*, 2009) is a tool for prioritizing candidate genes for inherited diseases. The candidate genes are ranked according to their possible relation to an inherited disease by applying a combination of data mining on biomedical databases and gene sequence analysis.

GeneDistiller (Seelow *et al.*, 2008) uses information from various data sources such as gene-phenotype associations, gene expression patterns and protein-protein interactions to obtain a prioritized list of candidates.

GeneFriends (van Dam *et al.*, 2012) a seed list of genes and functional annotation for candidate gene prioritization.

Gene Prospector (Yu *et al.*, 2008) prioritizes potential disease-related genes by using literature database of genetic association studies.

GeneRank (Morrison *et al.*, 2005) combines gene expression information with a network structure derived from gene annotations and returns a prioritized list of candidates.

GeneRanker (Gonzalez *et al.*, 2008) combines gene-disease associations with protein-protein interactions extracted from the literature to obtain a ranked list of genes potentially related to a specific disease or biological process.

GeneSeeker (Van Driel *et al.*, 2005) returns the genes that are located in the specified location and expressed in the specified tissue by accessing simultaneously at different databases.

GeneWanderer (Köhler *et al.*, 2008) is an algorithm that uses a global network distance measure to define similarity in protein-protein interaction networks. A candidate disease gene prioritization is obtained.

Genie (Fontaine *et al.*, 2011) ranks genes using a text-mining approach based on gene-related scientific abstracts and return a prioritized list of candidates and a selection of candidates.

Gentrepid (Jourquin *et al.*, 2012) predicts candidate disease genes based on their association to known disease genes of a related phenotype.

GLAD4U (Jourquin *et al.*, 2012) is a prioritization tool based that applies a ranking algorithm based on the hypergeometric test.

GPSy (Britto *et al.*, 2012) is a gene prioritization system that enables the rank process of a gene list or prioritization of the entire genome for the chosen species. In GPSy, only two types of diseases are available for the analysis.

GUILD (Guney and Oliva, 2012) is a network-based framework that computes the prioritization of genes using seven different algorithms. The ranking process is based on a priori gene-disease associations and protein interactions. GUILD can be downloaded.

MedSim tool (Schlicker *et al.*, 2010) ranks a list of genes for a known disease with a valid OMIM id, involving the Gene Ontology annotations. The classification is computed using two semantic similarity measures, (Lin and SimRel) on tree ontologies, Biological Process (BP), Molecular Function (MF), Cellular Component (CC). It receives as input a list of genes and a valid OMIM id.

MetaRanker (Pers *et al.*, 2011) enables the prioritization of the genome in relation to the phenotype of interest by integrating data sources for a given risk phenotype or disease.

MimMiner (Van Driel *et al.*, 2006) gathers the human phenome by text mining and ranks phenotypes according to their similarity to a given disease phenotype.

PGMapper (Xiong *et al.*, 2008) combines gene function information from the OMIM and PubMed databases and returns the candidate gene.

PhenoPred (Radivojac *et al.*, 2008) applies a supervised algorithm for detecting gene-disease associations based on the human protein-protein interaction network, known gene-disease associations, protein sequence and returns a prioritized list of candidates.

Pinta (Nitsch *et al.*, 2011) gathers information about the phenotype from experimental data in order to identify the most promising candidates.

PolySearch (Cheng *et al.*, 2008) ranks the relationships between diseases, genes, mutations, drugs, pathways, tissues by using a text mining system.

Posmed (Yoshida *et al.*, 2009) makes use of genomewide networks to obtain a Prioritized list of candidates and a selection of candidates.

PRINCE (Vanunu *et al.*, 2010) predicts causal genes and protein complexes involved in a disease of interest by using a network-based approach.

ProDiGe (Mordelet and Vert, 2011) uses a machine learning strategy which ensures to integrate various sources of information about the genes. The machine learning strategy is based on learning from positive and unlabeled examples and enable the prioritization of Disease Genes.

ProphNet (Martínez *et al.*, 2012) integrates information from data networks to return a prioritization gene list.

S2G (Gefen *et al.*, 2010) enables to search all diseases containing similar phenotypes given a disease and genes associated with these diseases. Furthermore, S2G enables to seek other genes that are associated with selected genes through the entire human genome.

SNPs3D (Yue *et al.*, 2006) identifies genes that are candidates for being involved in a specified disease based on literature.

TargetMine (Chen *et al.*, 2011) ensures a target prioritization within the framework of a data warehouse.

ToppGene (Chen *et al.*, 2009) is a web-based software able to rank candidate genes based on a similarity score for each annotation of each candidate with respect to selected disease. ToppGene requires an initial set of training genes to compare gene candidate terms.

Then, in the Gene Prioritization Portal are listed eight tools such as, Caesar, DGP, eResponseNet, Pandas, Pocus, Prioritizer, Suspects, Tom that are yet obsolete.

Moreover, there exists a gene prioritization tool, namely GoD (Gene on Diseases) (Cannataro *et al.*, 2015) that is not listed in the Gene Prioritization Portal but is reported in Omics Tool Page (see Relevant Website section).

GoD is provided as an R package. The current version of GoD enables the prioritization of a list of input genes with respect to a selected disease. The ranking is based on ontology annotations. In specific, GoD orders genes by the semantic similarity computed with respect to a disease among the annotations of each gene and those describing the selected disease. It is based on three ontologies: HPO ontology, GO ontology and DO ontology for the calculation of ranking. It takes as input a list of genes or gene products annotated with GO Terms, HPO Terms, DO Terms and a selected disease described in terms of annotation of GO, HPO or DO. It produces as output the ranking of those genes with respect to the input disease. The package consists of three main functions: hpoGoD (for HPO based prioritization), goGoD (for GO based prioritization) and doGoD (for DO based prioritization).

The hpoGoD function enables the prioritization of a list of input genes with respect to a disease described in terms of a list of HPO Terms using semantic similarity measures. For HPO, are applied the following semantic similarity measures: Resnik, JiangConrath, Lin, simIC, relevance, GIC and Wang (Wang *et al.*, 2010). Semantic similarities are calculated by using the HPOSim package (see Relevant Website section).

The goGoD function enables the prioritization of a list of input genes with respect to a disease described in terms of a list of GO Terms using semantic similarity measures. For this function, Resnik, Lin, Rel, Jiang and Wang measures are provided. The Semantic similarities calculated by using the GOSemSim package (Yu *et al.*, 2010).

The doGoD function computes the prioritization of a list of input genes in terms of a list of DO Terms with respect to a known disease with a valid DO ID and using one semantic similarity measure among Resnik, Jiang, Lin, Schlicker, and Wang, with BMA approach calculated by using the DOSE package (Yu *et al.*, 2015).

GoD algorithm guarantees a flexibility of data, dealing with different types of annotations from different ontologies. The user can adapt the input dataset according to the study to be investigated, and can analyze the data through tree kind of annotations,

choosing one function among hpoGoD.R, goGoD.R, doGoD.R. In fact, GoD, is able to make use of multi ontologies managing all the Gene Ontology sub-ontology (BP, MF, CC) and different ontologies like HPO and DO.

Illustrative Example(s) or Case Studies

This section presents the prioritization process of selected genes with respect to a selected disease by applying one tool among those cited, GoD. GoD enables the prioritization of a list of input genes with respect to a selected disease. It is based on GO, DO and HPO ontology for the calculation of ranking. It takes as input a list of genes or gene product annotated with GO Terms, HPO Terms, DO Terms and a selected disease. It produces as output the ranking of those genes with respect to the input disease. Package consists actually of three main functions: hpoGoD (for HPO based prioritization) , doGoD (for DO based prioritization), goGoD (for GO based prioritization). For these functions, the input file is a simple text file tab-separated containing for each line the gene identifier and its related annotations. The GoD web site provide an example input file that consists in an integrated dataset of DMET (Deeken, 2009; Arbitrio 2016) genes, related GO, HPO, DO annotations. The Affymetrix DMET (drug metabolism enzymes and transporters) Plus Premier Pack is a microarray able to analyze allelic variants in 225 genes related to, genes known to be related to drug absorption, distribution, metabolism and excretion (ADME). An experiment DMET consists of the selection of a set cases and a set of controls and the comparison of their genotypes. The result is a list of probes genes whose allelic variants are different in two classes.

To perform the prioritization analysis, the user may choose a subset of probe identifiers to analyze, a known disease with a valid OMIM ID and one semantic similarity measure.

Let an experiment has selected as candidate SNPs those identified by the following probes: AM_10183, AM_10178, AM_10174, AM_10168, the studied pathology is DUBIN-JOHNSON SYNDROME and the user want rank these genes by exploiting the HPO ontology. Thus, the user gives as input the list of these probes and the disease using the OMIM identifiers (see Relevant Website section) and select a semantic similarity from those provided by GoD. Since genes are annotated with HPO annotations, GoD calculates the semantic similarity among each of the input genes and the selected disease. Finally, GoD presents as output a histogram showing the semantic similarity values sorted from the higher to the lower in order to enhance the readability of results. A gradient of colors is also used to improve the readability.

In another example, an experiment has selected the following candidate identifiers set: AM_10163, AM_10155, AM_10143, AM_10121 and the user want to compute the prioritization of these input probes with respect to the breast cancer that is identified by D01216 in DO. In this case the user exploits the doGoD ontology to rank these genes. Similarly to the previous example, the user provides as input the list of identifiers, the disease identifier in DO and the selected semantic similarity. GoD calculates the semantic similarity among each of the input genes annotated with DO annotations and the selected disease.

Furthermore, It is also possible to compute the prioritization of the four probes identifiers with respect to Gene Ontology.

Results and Discussion

The results of omics experiments consist of a large list of genes, or gene products. However only to the behavior of few molecules is primary interest. Consequently, the need for the introduction of software tools able to help researchers to filter these lists on the basis of biological or clinical considerations e.g. which molecules are more related to a given disease arises. Identifying the most promising candidates among such large lists of genes is a challenge. In the past, the biologists manually obtained a candidates list by checking what is currently known about each gene, and assess whether it is a promising candidate. However, the bioinformatics community has introduced the concept of gene prioritization to take advantage of both the progress made in computational biology and the large amount of genomic data publicly available. Gene prioritization consists of the finding the most promising genes among large lists of candidate genes. Consequently, several gene prioritization tools have been developed to tackle this task, and some of them have been implemented and made available through freely available web tools. The informations about these tools are summarized in a website termed Gene Prioritization Portal that describes in detail the prioritization tools and it has been designed to help researchers to carefully select the tools that best correspond to their needs. These tools ensure the prioritization of human gene and differ by the inputs they need, the computational methods they implement, the data sources related to biological knowledge they use and the output they present to the user. Different tools such as MedSim, GUILD, ToppGene, GPSy, DomainRBF and GoD uses the knowledge contained in public ontologies to guide the selection process. In the case study, GoD is used to obtain the prioritization of DMET genes based on the use of annotation and semantic similarity measures. The advantages of using GoD for the prioritization process covers many aspects. GoD guarantees a flexibility of data, both dealing with different types of annotations from different ontologies and making use of multi ontologies managing all the Gene Ontology sub-ontology (BP, MF, CC). The use of annotations allows to evaluate any gene set and any disease without a training data set. Furthermore GoD uses the semantic similarity measures in the prioritization process of genes with respect to a selected disease. In this way, GoD assigns a value of similarity to ranked genes with respect to a known disease based on GO, HPO or DO annotations. GoD is also the only tool that provides a broad range of measures of similarity that the user can select. Finally, differently from the other tools, GoD is available for download as an R-package and its approach is customisable; thus the user may easily improve the analysis capabilities by inserting novel ontologies.

Future Directions

The progress of high-throughput technologies as well as the growth of genomic data direct the future directions of research towards the improvement of prioritization tools. In particular, the improvements have been conducted on the interface, which is sometimes overlooked in the software development process. Furthermore, these tools computed the prioritization process only among human genes; a future work regards the application of data available for species close to human.

Introduction

Research in bioinformatics was initially focused on the study of individual molecules and cellular components. Indeed, computers became essential to compare into an automated way multiple protein sequences, a task that was impractical to be made manually. Even if the reductionist method (Van Regenmortel, 2004) of studying the individual components (such as proteins, DNA, RNA and small molecules) and their functions resulted in explaining the chemical basis of numerous processes within living organisms, during the years the limitations of such approach have arisen. Indeed, biological systems are extremely complex and some behaviors cannot be explained by studying their individual parts only, since they frequently function in different ways in different processes. Instead, new biological characteristics, which are absent in the isolated components, arise as network behavior, that is from the way in which these components interact with one another. Such emergent properties of biological systems cannot be understood or predicted by simply analyzing their components. This is why bioinformaticians has increasingly shifted their interest from individuals to large-scale networks of interactions. In this respect, a key challenge is to understand and analyze the structure and the dynamics of such networks of interactions that contribute to the living functions of cells.

The study of biological networks has been facilitated by two factors. On the one hand, high-throughput data-collection techniques allowed to identify active molecules in biomolecular pathways. On the other hand, some technology platforms, such as yeast two-hybrid screening, helped to discover how and when these molecules interact with each other. As a result, by combining the discovered interactions, several types of biological networks has been generated, including protein-protein interaction, metabolic, signaling and transcription regulatory networks. It is important to note that even if such networks are often studied independently from one another, they actually form a 'network of networks'. In fact, they altogether determine the behavior of the cell.

It is interesting to point out that by applying the theory of complex networks to biological networks, it has been detected that the organizing principles that govern the formation and evolution of molecular interaction networks within a cell are similar to those of other complex systems, such as the Internet and social networks. This suggested that the laws that govern most complex networks in nature are similar and, thus, the knowledge from non-biological systems can help in characterizing biological networks. Indeed, similarly to other non-biological networks, networks of biological interactions are often represented as graphs, the nodes of which represents individual molecules and edges represent the interactions between them.

This article introduces the different types of biological networks. The rest of the article is organized as follows. In Section Networks in Biology the various type of biological networks are introduced and then discussed in depth in the subsequent sections, in particular: gene regulatory network are discussed in Section Gene Regulatory Networks, signaling network in Section Signaling Networks, metabolic network in Section Metabolic Networks, protein-protein interaction networks in Section Protein-Protein Interaction Networks and gene co-expression networks in Section Gene Co-Expression Networks. In Section Applications some applications of biological networks are discussed. Finally, in Section Closing Remarks some conclusions are drawn.

Networks in Biology

Molecules inside the cell interact with each other determining the biological processes at the basis of the cell's life. A set of molecules that are connected by physical interactions form a molecular interaction networks. Since molecular interactions can occur between molecules belonging to different biochemical families (e.g., proteins, genes, metabolites) and also within a given family, interaction networks are usually classified by the nature of the molecules involved. As an example, a well studied interactome is the protein-DNA interactome, that results in gene-regulatory networks. Such networks are formed by transcription factors, chromatin regulatory proteins, and their target genes. Gene-regulatory networks are discussed in Section Gene Regulatory Networks.

A key issue in biology is cell signaling, that is the response of a cell to internal and external stimuli and coordinate the regulation of its activity. Signaling networks are made up of highly connected modules that regulate some functions in the cell. Signaling networks are described in Section Signaling Networks.

A slightly different type of biological network are metabolic networks. Such networks are composed by cellular constituents and reactions that convert metabolites, i.e., chemical compounds in a cell, into each other. Such process is regulated by enzymes, which have to bind their substrates physically. Metabolic networks are presented in Section Metabolic Networks.

Another example of biological networks is the interactome of an organisms that refers to its set of protein-protein interactions. Such interactions generates protein-protein interaction networks. In many application it makes sense to study a subset of PPI interactions that generate a subnetwork. Protein-protein interaction networks are illustrated in Section Protein-Protein Interaction Networks.

Another type of biological network is obtained by using gene expression data. Gene expression is the process by which the gene products are synthesised by using the information encoded into genes. In particular, co-expression analysis allows to study existing patterns in gene expression data and to identify groups of genes with correlated expression profiles. Gene co-expression networks are discussed in Section Gene Co-Expression Networks.

Gene Regulatory Networks

The transcription of a gene to an mRNA molecule is regulated by proteins referred to as transcription factors. Transcription factors are proteins or protein complexes that contain at least one DNA-binding domain (DBD), which can bind to a specific sequence of DNA referring to the genes that they regulate. In particular, by binding to such DNA regions they activate (or upregulate) or inhibit (or downregulate) the production of another protein. In more details, transcription factors activate (resp., inhibit) the expression of a gene inside the cell by binding to regions upstream (resp., downstream) of the gene on the DNA molecule. This process may, in turn, facilitate or prevent RNA polymerase from binding and initiating the transcription of the gene. Thus, the genes inside cells interact with each other via intermediate transcription factors to influence each others expression.

In unicellular organisms, gene regulatory networks are essential to regulate the cell activity to survive to external environmental conditions. In multicellular organisms, such networks serve the purpose of regulating cell activity depending on the particular function the cell has to perform. This is essential when a cell divides and the two resulting cells, even containing the same genome, can differ in functions depending on which genes are activated or not. Moreover, some proteins resulting from the activation due to some transcription factors can pass through cell membranes and create signaling paths to other cells.

The regulation process can involve more than one transcription factor and a gene product can indirectly downregulate or upregulate another gene product through a chain of regulations. Moreover, cycles of regulation can generate feedback loops through which a gene product can downregulate or upregulate its own production. Negative feedback loops result in down-regulation, indicating for example that the transcript levels are kept constant or proportional to a factor. Positive feedback loops result in upregulation.

The set of genes interactions, both activations and inhibitions, inside the cell is referred to as the gene regulatory network.

Modeling

Various models have been proposed for gene regulatory networks. These models can be divided into three classes. The first class is that of *logical models*, which describe gene regulatory networks from the qualitative point of view. They can be adapted to fit biological phenomena but can only answer qualitative questions such as to understand if a gene is activated or not at some stage of the life of the system. For a finer grain analysis, when also quantitative information are needed (e.g., the concentrations of molecules) a second class of models, that is *continuous models*, has been developed. A third class of models, that is *single molecule level models*, takes into account the noise that can affect the functionality of regulatory networks. Some review works on the different types of modeling techniques can be found in the literature (Alakwaa, 2014; Karlebach and Shamir, 2008).

The basic logical model to represent gene regulatory networks is a Boolean network (Glass and Kauffman, 1973; Kauffman, 1993). A Boolean network is a directed graph the nodes of which are in one-to-one correspondence with genes and have associated Boolean variables. A value equals to 0 is associated to nodes whose corresponding gene is not expressed; a value equals to 1 is associated to nodes whose corresponding gene is expressed. In particular, each node (i.e., gene) has associated a Boolean function, that determine its Boolean value, that depends only from the Boolean values of its parent nodes. The state of the Boolean network is the set of values of the nodes and can change during time to model the evolution of the biological system. However, very often, due to insufficient understanding of the biological system to model, for each node in the network there is more than one possible boolean function that generate its state. To overcome the limitation imposed by Boolean networks, that allow to use one function only, another model, called Probabilistic Boolean networks (Shmulevich et al., 2002, 2003), has been proposed. Probabilistic Boolean networks modify Boolean networks by associating to each node several regulation Boolean functions each of which has associated a probability. Thus, at each time step the function to apply at each node is determined randomly according to the given probabilities.

Another logical model used for gene regulatory networks are Bayesian networks (Chen et al., 2006; Friedman et al., 2000), that are probabilistic directed acyclic graph models that represent a set of random variables (i.e., the genes' expressions) and their conditional dependencies (i.e., activation or inhibition) via a directed acyclic graph.

To analyze the dynamics of gene regulatory network a good model to use are Petri nets (Steggles et al., 2007). A Petri net is a directed bipartite graph having two types of nodes, that are transitions, represented by bars, and places, represented by circles. The directed arcs, denoted by arrows, describe which places are pre- and/or post-conditions for which transitions. Arcs run from a place to a transition or vice versa. Moreover, tokens, represented by black dots inside some places, enable transitions to fire.

A shortcoming of logical models is that they require the discretization of the input data. However, experiments that measure gene-expression intensities produce real values. This motivated the adoption of continuous models that use real-valued parameters. A basic type of continuous model are linear models (Weaver et al., 1999), that are based on the assumption that each regulator contributes to the regulation of the same gene independently from the other regulators. This translates into regulation functions that are weighted linear sums of the levels of the regulators.

A more general model is based on differential equations instead of linear functions (Chen *et al.*, 2004; Li *et al.*, 2008). Differential equations allow to explicitly model the concentration changes of molecules over time. Thus, it is a better model to study the dynamics of the network since it allows to follow concentration changes continuously, even when the time increase considered is infinitely small.

To conclude, it has been observed that the behavior of biological systems is not deterministic, in the sense that it can evolve differently even starting from the same initial state. Such source of non-determinisms can be modeled by stochastic approaches (Gillespie, 2007). Such approaches attempt to describe the time evolution of the system by taking into account the systems stochasticity by using probability functions.

Signaling Networks

Cells have the ability to receive and process signals that originate outside their borders in order to respond to changes in their immediate environment. In particular, inside the cell there are particular proteins, called receptors, that bind to signaling molecules and initiate the response process. Receptors are generally transmembrane proteins that are able to bind signaling molecules that are outside the cell and then transmit the stimuli inside the cell. There are different types of receptors that can bind different signaling molecules. Moreover, different cell types have different populations of receptors.

Individual cells often receive many signals simultaneously and integrate the different stimuli to define a unified action plan. Most cell signals correspond to chemical characteristics such as growth factors, hormones or neurotransmitters. However, some cells are also able to respond to mechanical stimuli, such as sensory cells in the skin that respond to the pressure of touch. The response reaction of a cell can be for example the activation of a gene or the production of energy. The capacity of the cell to receive and correctly respond to the environmental stimuli is essential for cell development. Indeed, malfunctioning in stimuli processing is responsible for diseases such as cancer and diabetes.

Cells are usually specialized to perform some specific functions and, thus, to carry out complex biological processes several cells need to cooperate and coordinate their activities. Hence, cells have to communicate with each other to respond in an appropriate manner to specific environmental stimuli. Such communication is made possible by a process called cell signaling. The overall process that transform the external signals into changes that occur inside the cell is called signal transduction. Signal conversions usually involve sequences of chemical reactions among proteins. The signal transduction networks or signaling networks store information about the processes through which cells respond to stimuli. Signaling can be subdivided in the following five classes:

- Intracrine: refers to signals that are produced inside a cell and remain inside the cell;
- Autocrine: refers to signals produced inside a cell, secreted to the external environment, and that affect the same cell (or close-by cells of the same type) via receptors;
- Juxtacrine: refers to signals produced by a cell that affect adjacent cells via cell membrane contact;
- Paracrine: refers to signals produced by a cell that affect nearby cells (does not require cell contact);
- Endocrine: refers to signals produced by a cell that can reach cells in other parts of the body via the circulatory system.

Another way to classify signaling is with respect to the signaling molecule. Three major classes of signaling molecules can be identified:

- Hormones: they are the major signaling molecules of the endocrine system and, often, they regulate each other's secretion. They are used to communicate for physiological regulation and behavioral activities such as metabolism or sleep.
- Neurotransmitters: they are signaling molecules of the nervous system.
- Cytokines: they are signaling molecules of the immune system.

Modeling

Signaling networks can be represented at a qualitative level by a graph the nodes of which are molecules and the edges of which represent the capability of molecules to activate or deactivate other molecules. The qualitative approach allows to perform statistical analysis of signaling networks and to identify some structural properties about single elements of the network, clusters of elements, or the entire network, such as node degree (the number of edges connected to a node) or the shortest path between two nodes.

The qualitative approach, however, does not allow to take into account the temporal evolution of signaling networks occurring under different conditions. Quantitative models extend qualitative models in this direction. Systems of Ordinary Differential Equations (ODE) have been largely used for the quantitative modeling of signal transduction networks. They represent a biological system by a set of mathematical equations, each of which rules the temporal evolution of a molecule. Even if they are widely used, ODE models have some drawbacks among which the fact that defining the equations is a very difficult task. To overcome the drawbacks of ODE models, several network-oriented and bio-inspired models have been introduced that allow to symbolically describe signaling processes. Among them, there are P systems (Paun, 2000), or membrane systems, a computational model which takes its inspiration from the structure and functioning of the cell, and in particular from the way in which chemicals interact and cross cell membranes. The P system has a particular membrane structure that subdivides it compartments. The compartments

contain objects (described by symbols or by strings of symbols) which evolve according to some given rules. By applying the rules in a nondeterministic, parallel manner, transitions between the system configurations are determined.

Metabolic Networks

The growth and maintenance of the cell is performed via biochemical reactions responsible for the up-taking of nutrients from the external and their conversion into other molecules. Each reaction, that is a transformation of chemical substances or metabolites (reactants) into other substances (products), is usually catalyzed by enzymes. In general metabolic reactions are reversible, that is, they occur in both directions; but, if considered in isolation, each reaction reaches a steady state that is a state where the amount of change in both directions is equal. However, the cell continuously exchange substances with the environment and other factors can affect the reactions. Thus, the steady states can be shifted and it can be recognized a main direction for a reaction (this is why usually one distinguish between reactants and products). Moreover, metabolic reactions interact with each other, that is the product of one reaction can be a reactant of another reaction. A sequence of metabolic reactions $P = (R_1, \dots, R_n)$ such that at least one product of the reaction R_i is a reactant for the reaction R_{i+1} , for all $i \in \{1, \dots, n-1\}$, is called a path of reactions.

The metabolic network of a cell or an organism is its complete set of metabolic reactions. The complete metabolic networks of several organisms, from bacteria to human, can be reconstructed thanks to the sequencing of complete genomes. Indeed, several of these networks are available online and can be freely downloaded from several databases such as Kyoto Encyclopedia of Genes and Genomes (KEGG) (Kanehisa and Goto, 2000) or EcoCyc (Keseler et al., 2005). A metabolic pathway is a connected sub-network of a metabolic network that usually represents a specific process. Metabolic pathways can be also constructed by defining their functional boundaries, for example, by defining an initial and final metabolite.

The substances that participate to a metabolic pathway are often divided into two types: the main substances and the co-substances, that are small metabolites, such as ATP or ADP. However, such subdivision is not a global property but depends on the reaction under consideration, meaning that the co-substances for a reaction can be considered as main substances for another reaction. Such a distinction is mainly used by visualization tools that generally visualize main and co-substances in a different manner.

During the years, many simplifications of metabolic networks have been used in the literature such as:

- Simplified metabolic networks (Bachmaier et al., 2014) that are networks that contains reactions, enzymes and main substances, but no co-substances.
- Metabolite networks and simplified metabolite networks (Risler et al., 2006) that are networks consisting only of substances (metabolites) and, in the simplified case, only of main substances.
- Enzyme networks (Xiong et al., 2016), that are networks consisting only of the enzymes catalyzing the reactions.

Modeling

The simplest model to represent a metabolic network is via an hyper-graph. The nodes of the hyper-graph represent the substances and the hyper-edges represent the reactions. A hyper-edge involves all substances of a reaction, is directed from reactants to products and can be labeled with the enzymes that catalyze the reaction. Hyper-graphs can be represented by directed bipartite graphs. A directed bipartite graph, indicated as $G = (V_S, V_R, E)$, is a directed graph having two partitions of nodes, V_S and V_R . Here, nodes in V_S represent substances, nodes in V_R represent reactions (and are labeled with the enzymes that catalyze the reaction) and directed edges in $E \subseteq (V_S \times V_R) \cup (V_R \times V_S)$ represent the transformation of substances. In particular, the set of edges $(u_1, r), \dots, (u_n, r), (r, v_1), \dots, (r, v_m)$ encodes the fact that the reaction r transforms the reactants $u_1, \dots, u_n$ into the set of products $v_1, \dots, v_m$ (and encode the hyper-edge involving $u_1, \dots, u_n, v_1, \dots, v_m$ representing r). In the bipartite metabolic graph, there are no direct links between either two metabolites or two reactions.

Another bipartite graph representation of metabolic networks $G = (V_S, V_E, E)$ considers as the two partitions of nodes the chemical compounds (V_S) and the enzymes (V_E), respectively. For each enzyme node, an incoming edge occurs with each of its substrate nodes and an outgoing edge occurs with each of its product nodes, i.e., $E \subseteq (V_S \times V_E) \cup (V_E \times V_S)$.

Metabolic networks can be also modeled via weighted tripartite graphs $G = (V_S, V_R, V_E, E_R, E_E)$, that have three types of nodes representing metabolites (V_S), reactions (V_R) and enzymes (V_E), respectively, and two types of edges representing mass flow (E_R) and catalytic regulation (E_E), respectively. The first type of edge connects reactants to reactions and reactions to products (i.e., $E_R \subseteq (V_S \times V_R) \cup (V_R \times V_S)$). The second type connects enzymes to the reactions they catalyze (i.e., $E_E \subseteq (V_E \times V_R)$).

Another possible simpler model is based on the use of graphs (which could be directed or undirected) having one type of node only. For instance, if one considers nodes as representing enzymes, directed edges connecting pairs of enzymes represent the fact that the product of the first enzyme is a reactant of the second enzyme. If one considers nodes as representing metabolites the directed edges represent enzymes that catalyze a reaction having the first metabolite as a reactant and the second metabolite as a product.

More complex models involve the use of Ordinary Differential Equations (ODE) or P systems and, in particular, of Metabolic P systems, shortly MP systems (Manca and Luca, 2008), that are particularization of P systems applied to metabolic networks.

Protein-Protein Interaction Networks

Proteins are the main agents of biological function. Indeed, proteins control molecular and cellular mechanisms and, thus, determine healthy and diseased states of organisms. However, they are not functional in isolated forms but they interact with each other and with other molecules (e.g., DNA and RNA) to perform their functions. Thus, the study of proteins' interactions is crucial to understand their role inside the cell. Since this type of interactions can be of several types, the term *protein-protein interaction* refers to a variety of events happening inside the cell. As an example, a protein-protein interaction can indicate the formation of either stable or transient protein complexes as well as either physical or functional interactions.

A protein-protein interaction network stores the information about the protein-protein interactome of a given organism, that is the whole set of its protein-protein interactions. Even if it has been suggested that the size of protein-protein interactomes proportionally grows with the biological complexity of the organisms, none protein-protein interactome has been completely identified and, thus, this correlation only remains a conjecture. Moreover, the available protein-protein interaction networks are error-prone due to the fact that experimental methods used to discover interactions may include false positives or there may unveil some existing interactions.

There are a multitude of methods that have been proposed to detect protein-protein interactions and populate protein-protein interaction networks. In general, none of them is better than the others but each method has its own strengths and weaknesses. The goodness of a method is measured in terms of its sensitivity (high sensitivity corresponds to the ability of the method to discover many real interactions) and specificity (high specificity indicates that most of the interactions detected are real interactions). Thus, to each protein-protein interaction can be associated a weight that takes into account the sensitivity and specificity of the method used to discover it. The methods commonly used to detect protein-protein interactions can be classified in two main groups: experimental and computational methods. The experimental methods can be divided in their turn in two classes: (i) biophysically methods that represent the main source of knowledge about protein-protein interactions and are based on structural information (e.g., X-ray crystallography, NMR spectroscopy, fluorescence, atomic force microscopy); and (ii) high-throughput methods, that can be either direct or indirect. Among the direct high-throughput methods there is the Yeast two-hybrid (Y2H) that examines the interaction of two given proteins by fusing each of them to a transcription binding domain. Indirect high-throughput methods are based on the use of other types of experimental data such as gene co-expression data. Experimental methods, even if being accurate, have some severe drawbacks: they are expensive and time consuming. This motivated the adoption of computational methods that are fast and cheap. Computational methods can be subdivided in two classes: (i) empirical predictions that use experimental data to infer new protein-protein interactions; and (ii) theoretical predictions that use some accepted assumptions to predict protein-protein interactions. The main drawback of empirical prediction is that by exploiting experimental data they naturally propagate errors and inaccuracies.

Although protein-protein interaction networks are incomplete and error-prone, they are particularly important in many contexts. For example, the analysis of such networks facilitates the understanding of the mechanisms that trigger the beginning and progression of diseases. Moreover, protein-protein interaction networks have been used to discover novel protein function ([Fionda et al., 2009](#)) and to identify functional modules and conserved interaction patterns ([Fionda and Palopoli, 2011](#)).

Some studies on the structure of the protein-protein interaction networks of several species allowed to discover that independently from the species, protein-protein interaction networks are scale-free. It means that some hub proteins have a central role participating in the majority of the interactions while most proteins, that are not hubs, only participate to a small fraction of interactions.

In the literature there exists another type of biological network that is strictly related to protein-protein interaction networks: domain-domain interaction (DDI) networks. Domains are independently folded modules of a protein and a domain-domain interaction (DDI) network is constructed by replacing each protein in a protein-protein interaction network by one or more nodes representing its constituent domains. In this type of network, each edge that in the protein-protein interaction network connected two proteins is transformed in an edge connecting the corresponding domain nodes. Since most of the known proteins are composed by more than one domain, a domain-domain interaction network usually is much larger than the protein-protein interaction network from which is extracted.

Modeling

Protein-protein interaction networks are commonly modeled via graphs, whose nodes represent proteins and whose edges, that are undirected and possibly weighted, connect pairs of interacting proteins. Edge weights may be used to incorporate reliability information associated to the corresponding interactions.

It is important to point out that, since protein-protein interactions are often obtained from protein complex detection and not really as binary interactions, a more complex model may be more suitable for the representation of protein-protein interaction networks. In fact, the use of hyper-graphs, instead of simple graphs, allows to model protein complexes, where each hyper-edge involves all proteins belonging to the same complex.

Gene Co-Expression Networks

Gene expression is the process by which the information encoded in a gene is used to synthesize a gene product (i.e., a protein or RNA). Transcription is the first step of gene expression, in which the DNA of the gene is copied into RNA. Gene co-expression

networks store information about transcription that takes place at the same time or under the same conditions. Differently from gene regulatory networks (see Section Gene Regulatory Networks), gene co-expression networks do not provide any information about the causality relationships between genes (e.g., activation or inhibition) and edges only represent the fact that there exists a correlation or dependency relationship among genes.

Several methods have been developed for constructing gene co-expression networks and they are all composed by two main steps: (1) calculating a co-expression measure, and (2) selecting a significance threshold. The first step is usually carried out by exploiting high-throughput gene expression profiling technologies such as large-scale DNA microarray experiments. In particular, starting from microarray gene expression data for several samples or experimental conditions, a gene co-expression measure can be obtained by looking for pairs of genes that show a similar expression pattern across samples. The input data is often represented as a matrix, whose columns represent genes and whose rows represent the different samples or conditions. Such a matrix is called expression matrix. A numerical value to quantify the similarity of the expression profiles of genes can be obtained according to several measures such as the Pearson's correlation coefficient, Mutual Information, Spearman's rank correlation coefficient or Euclidean distance. In particular, the correlation of two genes is computed by comparing different rows of the expression matrix and computing a numerical similarity value for the two genes according to the selected measure. If all pairs of genes are considered a correlation matrix (whose rows and columns both represent genes) can be built, where each element shows how similar the expression levels of two genes are. As for the second step, a threshold is selected such that gene pairs which have a correlation score higher than the threshold are considered to have significant co-expression relationship. Then, the elements in the correlation matrix which are above then threshold are replaced by 1 (meaning that the corresponding genes are similarly co-expressed) and the remaining elements are replaced by 0.

Clearly, each of the above mentioned correlation measures have its own advantages and disadvantages. However, the Pearson's correlation coefficient is the most popular co-expression measure. The Pearson's correlation coefficient takes a value between -1 and 1 where values close to 1 or -1 show strong correlation. In particular, positive values correspond to positive correlation meaning that the expression value of one gene increases with the increase in the expression of its co-expressed gene and vice versa. Negative values correspond to negative correlation meaning that the expression value of one gene decreases with the increase in the expression of its co-expressed gene.

There exist also several methods to select the threshold value. The simplest approach consists in choosing a co-expression cutoff without looking at the data. Another approach is to use Fisher's Z-transformation that first calculates a z-score based on the number of samples and then converts the z-score into a p-value used to set the threshold.

The study of gene co-expression networks allows to identify genes that are controlled by the same transcriptional regulatory program, that are functionally related, or whose gene products are involved in a common biological process.

Modeling

According to the way gene co-expression networks are built the simplest model to represent them is by using the correlation matrix (in particular the matrix containing only 0 and 1 s obtained after applying the threshold) to build a graph. In particular, such binary adjacency matrix corresponds to an unweighted graph the nodes of which represent the genes and whose edges connect genes that are co-expressed. According to such a model all connections are equivalent.

A more complex model takes into account edge weights to store information about the corresponding values in the correlation matrix (before applying the threshold). In particular, in such a representation the graph is complete, meaning that there exists an edge between each pair of nodes, and the strength of the connection (i.e., co-expression) is given by the edge weights.

Applications

Biological networks found application is several research areas. As an example, the analysis of biological networks with respect to human diseases has led to the field of network medicine ([Barabási et al., 2011](#)). Indeed, a disease is usually a consequence of an abnormality in a complex intracellular and intercellular network and the study of biological networks can help in characterizing diseases. For instance, biological networks are analyzed to discover disease-gene associations with the aim of identifying relationships between disease phenotypes and genes. Even if traditional approaches, that do not use biological networks, are successful, often it is necessary to analyze experimentally tens or even hundreds of genes. To reduce experimental cost and efforts, protein-protein interaction networks or metabolic networks are used by disease gene prioritization methods to rank candidate genes that are probably related to a disease.

Another application of biological networks in network medicine is for the genome-wide association study (GWAS). The GWAS aims at studying DNA sequence variations in the human genome to discover their associations with diseases (or phenotypes). In particular, the network-based GWAS methods are based on two types of information: (i) interactions between genes or proteins and (ii) association information available from an existent GWAS.

Protein-protein interaction networks are widely used for predicting protein function. The standard way to predict protein function is based on the computation of sequence homology that is used to annotated proteins. However, for the great majority of proteins their function still remains unknown. Protein-protein interaction networks have been successfully used in this context and several approaches to predict protein function by analyzing this type of network have been proposed (e.g., [Fionda et al., 2009](#)).

Another area of application of biological networks regards complex networks. Complex networks research helps in representing, characterizing and modeling complex systems and phenomena and, thus, found a natural application in the analysis of biological networks (Costa *et al.*, 2008).

Closing Remarks

The various types of biological networks have been discussed in the previous sections independently from one another. However, it is important to underline that they are not independent inside the cell. For instance, on the one hand the state of the genes in the transcriptional regulatory network determines the activity of the metabolic network. On the other hand, the concentration of metabolites in the metabolic network determines the activity of transcription factors or proteins which regulate the expression of genes in the regulatory network. Thus, all the different types of biological networks form together a network of networks inside the cell that determines the overall behavior of the corresponding organism.

Indeed, several research groups have integrated different types of networks in their studies. As an example, gene expression networks have been integrated with protein-protein interaction networks in order to understand how one of them affect the other in different biological states. For example, the protein-protein interaction network of the yeast was merged with the gene expression network and the results showed that on the one hand most proteins of interacting complexes are expressed in a similar manner in the various stages of the cell cycle, and on the other hand, only a single or a small number of key proteins are expressed in a single phase. Thus, the complementing of these two types of networks allowed to identify such key elements.

Introduction

Nowadays, even in our daily life, we encounter several different situations in which objects, or more in general elements, are put into relations or simply connected with other objects, creating a network. Although in most cases it is not easy to spot these kind of structures, they are widely adopted and used for different purposes. As an example, if we consider a city map, cities and towns are the elements and streets represent the connections among them. The same is also valid for maps of the underground of a city or of the railway connections among different places. These very intuitive and easy to understand structures are called *graphs* and, although simple, they have a formal mathematical formulation on which several properties are defined. Moreover, in fields like computer science they constitute the basis of different data structures, which are then used by algorithmic procedures to efficiently solve specific problems. As an example, satellite navigators exploit a graph structure representing the map of the area of interest to find the best way to reach a specific location from the actual position. Recalling the previously mentioned example, in a simpler way, we solve the same problem when we decide which trains to take to go from a point A to a destination B, following the railway map.

As anticipated before, graphs are widely used in several different fields, ranging from mathematics to biology, and from computer science to physics. One of the main reasons of their widespread adoption is due to the fact that graphs are able to capture and model different real case scenario, helping scientists in finding solutions to specific problems. In fact, although graphs offer a simple and very intuitive graphical representation, they have a formal mathematical definition, on which several properties and algorithms are based (Cormen *et al.*, 2009; Diestel, 2012).

Mainly thanks to these aspects, two of the most influenced research fields in which graphs are employed are bioinformatics and systems biology (Doncheva *et al.*, 2012). In fact, since graphs are usually adopted to model relations between elements in biological datasets, several real case studies, like the analysis of the chromatin conformation inside the nucleus of cells (Merelli *et al.*, 2013; Tordini *et al.*, 2016) or the identification of biological pathways in gene regulatory networks (Karlebach and Shamir, 2008), take advantage of this formalism to efficiently represent and analyze the data. Other examples are their application to protein-protein interaction networks (Pizzuti and Rombo, 2014), in which are mainly employed for clustering analysis.

Graphs are also extensively studied, from a formal point of view, in computer science where they are fundamental tools for solving computational problems. For this reason, several bioinformatic approaches and tools rely on them to implement algorithms for solving biological problems, like genome assembly, sequence alignment, or Next-Generation Sequencing reads error correction. More precisely, and as an example, mapping nucleotidic reads to a gene transcript can be modeled as the alignment of sequences to a graph that represent the possible alternative splicing events (Beretta *et al.*, 2014). In the same context, to perform the assembly of molecular sequences, the majority of the developed techniques rely on a graph structure to face this problem, like building an overlap graph of the input short fragments, and then extracting the sequence of nodes that better represents the original one (Bonizzoni *et al.*, 2016; Myers *et al.*, 2000; Simpson and Durbin, 2012), or constructing the de Bruijn graph of the input long fragments, and then finding the different paths corresponding to the expressed gene transcripts (Grabherr *et al.*, 2011; Trapnell *et al.*, 2010).

Moreover, due to the novel developments in the aforementioned fields that lead to the production of huge quantities of data to be analysed, the role of structures like graphs is becoming more and more central. In fact, in order to develop more efficient techniques to deal with such data, graphs are often employed to design optimal procedures and also to achieve good performances from the applicative point of view (Gonnella and Kurtz, 2012).

For these reasons, a good knowledge of the graphs is fundamental to understand the majority of the state-of-the-art methods that deal with problems in bioinformatics and systems biology. In this article we will introduce the basic concepts and definitions of graphs and we will highlight their usage in bioinformatics and systems biology.

Background

A graph G is a pair $G=(V, E)$ where V is the set of vertices (also called nodes) of size $|V|$, and $E \subseteq V \times V$ is the set of edges. Each edge $e \in E$ is an element that *connects* two vertices in V and that represents some kind of relation between them. If e connects the nodes u and v , then it is common to refer to e as the pair $\{u, v\}$. The vertex set of the graph G is also referred to as $V(G)$, while its edge set as $E(G)$. Depending on the meaning of the relations between nodes, a graph can be either *directed* or *undirected*. In the former case, the connections between pairs of nodes are usually called *arcs*, and each arc e has an *orientation* so that e is represented as an ordered pair of vertices (u, v) with $u, v \in V$. In the latter case, edges do not have orientations and an edge e can be represented either as $\{u, v\}$ or $\{v, u\}$. Note that in directed graphs the ordering between the nodes in the arcs has a fundamental role and, therefore, two arcs $e_i=(u, v)$ and $e_j=(v, u)$ represent two different arcs (if $u \neq v$). Recalling the previously introduced examples, directed graphs can be used in biological networks and especially in metabolic networks to model the pathways of enzymes and metabolites (Bourqui *et al.*, 2007).

Moreover, given a vertex $v \in V$, the edge $\{v, v\}$ is called *loop* and, usually, graphs without loops are called *simple graphs*.

Following the previous distinction based on fact that arcs and edges are different concepts, a graph $G = (V, E)$ is graphically represented by drawing for each vertex $v \in V$ a dot and, for each edge $e \in E$ between vertices u and v , either a line connecting u and v if the graph is undirected, or an arrow directed towards v if the graph is directed.

Fig. 1 shows an example of an undirected graph (**Fig. 1(a)**) and an example of a directed graph (**Fig. 1(b)**). As one can see from these figures, the undirected graph in **Fig. 1(a)** has an edge connecting nodes u and v , while the one in **Fig. 1(b)** has two arcs linking the same nodes, i.e., (u, v) and (v, u) . The same also applies to nodes w and x of the examples in the same figures.

In the rest of this article, we will refer all the concepts and the definitions to a graph $G = (V, E)$ using the notations for undirected graphs if they apply to both directed and undirected graphs, while we will explicitly highlight the differences between the two when required.

The graph $G = (V, E)$ such that $V = \emptyset$ and $E = \emptyset$ is called *empty graph*.

Given an edge $e \in E$, with $e = \{u, v\}$, the vertices u and v are called *adjacent* or *neighbor* vertices and are said to be *incident* with e . More precisely, if G is an undirected graph, $e = \{u, v\}$ is usually said to be *incident on* both vertices u and v , whereas if G is a directed graph, $e = (u, v)$ is said to be *incident from* or *leaving* vertex u and *incident to* or *entering* vertex v . The set of all edges entering or leaving a vertex v is usually denoted by $E(v)$.

Let $G = (V, E)$ and $G' = (V', E')$ be two graphs, if $V' \subseteq V$ and $E' \subseteq E$, then we say that G' is a *subgraph* of G and that G is a *supergraph* of G' . In the following we will denote the subgraph and supergraph relations using the $\subseteq$ and $\supseteq$ symbols, respectively. More precisely, if G' is a subgraph of G then we will denote it by $G' \subseteq G$. Let $G = (V, E)$ be a graph and let V' be a subset of V , that is $V' \subseteq V$. Then, the subgraph of G induced by V' is the graph $G' = (V', E')$, where E' is the set of edges incident in the vertices of V' . More formally, we say that E' is the set $\{\{u, v\} \in E : u \in V' \wedge v \in V'\}$. An example of induced subgraph is shown in **Fig. 2**.

A *weighted* graph is a graph with an associated function f_w that assigns to every vertex or to every edge a value that is usually referred to as the *weight*. The function f_w is referred to as the *weight function*. Depending on whether the weight function's domain is the set of vertices or the set of edges, we can refer to a weighted graph either as a *vertex-weighted* graph or as an *edge-weighted* graph. Formally, a vertex-weighted graph is the union of a graph $G = (V, E)$ and a weight function $f_w: V \rightarrow \mathbb{R}$, while an *edge-weighted* graph is the union of a graph $G = (V, E)$ and weight function $f_w: E \rightarrow \mathbb{R}$. In the former case, given a vertex $v \in V$, the weight associated with v can be denoted as $f_w(v)$, while in the latter case of edge-weighted graph, given an edge $\{u, v\} \in E$, the corresponding weight can be denoted as $f_w(u, v)$. In bioinformatics, one of the applications of weighted graphs is in the assembly of sequences (genomes, transcripts, or meta-genomes) starting from a set of short reads which must be assembled. In such a case, the majority of the

Fig. 1 Examples of both undirected (a) and directed (b) graphs.

Fig. 2 Example of induced subgraph: starting from a graph $G = (V, E)$ (a), the subgraph $G' = (V', E')$ induced by the vertex set $V' = \{u, v, w, y, z\}$ is shown (b).

assembly algorithms employs a graph structure to reconstruct one or more paths corresponding to the solution and, to do so, weights are used to represent the support in terms of number of reads, which helps in discarding wrong solutions and reconstruct the correct one(s) (Zerbino and Birney, 2008).

A *bipartite* graph is a graph $G=(V, E)$ in which V can be partitioned into two disjoint subsets V_1 and V_2 such that the vertices contained in the same subset are not adjacent, i.e., all the edges of E are incidents on a vertex of V_1 and on a vertex of V_2 . Formally, given a graph $G=(V, E)$, then G is a bipartite graph if there exists two sets $V_1 \subseteq V$ and $V_2 \subseteq V$ such that the following properties are true:

- $V_1 \cap V_2 = \emptyset$;
- $V_1 \cup V_2 = V$;
- $\forall \{u, v\} \in E: (u \in V_1 \wedge v \in V_2) \vee (v \in V_1 \wedge u \in V_2)$.

An example of bipartite graph is shown in Fig. 3. Bipartite graphs are usually adopted to model two categories of elements, and the relations between elements belonging to the two different categories. Examples of this situation can be found, for example, when analyzing long non-coding RNAs (lncRNAs) with respect to their binding proteins, which results in a graph connecting nodes representing lncRNAs with others representing targeted proteins (Ge et al., 2016).

Finally, a *multigraph* $G=(V, E)$ is an undirected graph in which multiple edges can connect the same pair of vertices, that is E is a multi-set of edges. An example of multigraph is shown in Fig. 4. Multigraphs are important because in some cases there is the need of representing different types of information between two elements, each one with a different meaning.

One of the most important aspects when dealing with graphs is their representation since, in many cases, it can affect the performance of the methods that employ them. From this point of view, the two most commonly used representations of a graph $G=(V, E)$ are a collection of *adjacency lists* and an *adjacency matrix*.

The adjacency lists representation of a graph $G=(V, E)$ consists of an array *Adj* of lists having size $|V|$, that is, one for each vertex in the vertex set V , such that for each vertex $v \in V$, $Adj[v] = \{u \in V: \{v, u\} \in E\}$. This representation is recommended for *sparse* graphs, which are graphs having a small number of edges, i.e., $|E| \ll |V|^2$, where $|V|^2$ is an approximation of the maximum number of edges of a graph having $|V|$ vertices. In fact, this approach allows to store only the edges present in the graph and to keep the space required to store the graph G linear with its size. The drawback of this representation is that to search whether the edge $\{u, v\}$ is in

Fig. 3 Example of bipartite graph $G=(V, E)$, in which nodes can be partitioned into two subsets: $V_1=\{u, v, z, t\}$ (empty circle nodes) and $V_2=\{w, x, y\}$ (black circle nodes). Here, two different ways of drawing the bipartite graph G are shown.

Fig. 4 Example of multigraph.

the graph it is necessary to scan the whole adjacency list of u . This means that in the worst case scenario, that is, when each vertex is connected to all the others, this test requires $\mathcal{O}(V)$ time. The adjacency list of the graph shown in Fig. 1(a) is:

u	$= \{v, w, x\}$
v	$= \{u, w, y\}$
w	$= \{u, v, x, y\}$
x	$= \{u, w\}$
y	$= \{v, w\}$

On the other hand, for *dense* graphs in which $|E| \simeq |V|^2$, or in situations when the existence of an edge must be checked quickly, the adjacency matrix representation is more suitable. This representation of a graph $G=(V, E)$ consists of a $|V| \times |V|$ matrix A , such that

$$A[u, v] = \begin{cases} 1 & \text{if } \{u, v\} \in E \\ 0 & \text{otherwise} \end{cases}$$

This way of representing a graph requires a fixed $|V|^2$ bits space but allows to test the presence of an edge in $\mathcal{O}(1)$ time. For this reason, storing a sparse graph using an adjacency matrix leads to a matrix having the majority of values set to zero, wasting space.

Moreover, if $G=(V, E)$ is a *edge-weighted* graph, the matrix A can be adapted to store the weights of the edges, instead of the only presence or absence of a connection, i.e., 0 and 1, respectively. More precisely, $A[u, v]=f_w(u, v)$, that is the weight associated with the edge $\{u, v\} \in E$, and 0 otherwise, that is, if $\{u, v\} \notin E$.

The adjacency matrix of the graph shown in Fig. 1(a) is:

	u	v	w	x	y
v	0	1	1	1	0
w	1	0	1	1	1
x	1	1	0	0	1
x	1	1	0	0	0
y	0	1	1	0	0

Notice that both these representations can be applied to undirected and also to directed graphs. Anyway, it must be also noticed that for undirected graphs the adjacency matrix is symmetric and so $A[u, v]=A[v, u]$, for each $u, v \in V$, meaning that it is possible to consider only the upper triangular part (with respect to the diagonal). On the other hand, this is not valid for directed graphs, for which the two triangular parts (upper and lower) of the matrix contain the direction of the arcs, since $A[u, v]$ refers to the arc $(u, v) \in E$, while $A[v, u]$ refers to the arc $(v, u) \in E$.

Methodologies

In this section we will focus on bipartite graphs and, in particular, we will describe an algorithmic procedure to verify if a given graph is bipartite. This will be done without entering into the formal aspects of this problem, nor the technical algorithmic details of the procedure. In fact, the main aim of this part is to give an idea of a possible solution to the bipartite check problem, but also to give an example of how it is possible to design an algorithm working on graphs.

Bipartite graphs are quite interesting and are employed in several different studies and, for this reason, there is often the necessity to check if a given graph $G=(V, E)$ is bipartite or not. Although for small examples this check is quite easy and sometimes it could be done just by looking at the graphical representation of the graph, when the number of vertices grows this problem becomes harder. Since, by definition, in a bipartite graph the set of vertices V can be partitioned into two subsets, namely V_1 and V_2 , in such a way that there are no edges connecting two vertices belonging to the same subset, it is possible to assign a color to each vertex according to the subset it belongs. As an example, it is possible to color vertices of V_1 with "red" and those of V_2 with "blue", so that each edge will connect a red and a blue vertex. More precisely, in a bipartite graph the vertices can be colored with two colors, corresponding to the two subsets, so that the vertices incident to each edge will always have two different colors. This property is useful especially in determining if a given graph $G=(V, E)$ is bipartite or not. In fact, it must be observed that if there is a subgraph composed of three vertices, in which every vertex is adjacent to the other two, i.e., a "triangle", it is not possible to

assign two colors, say red and blue, in such a way that adjacent vertices will have different colors. Let us consider the subgraph composed of three vertices u, v, z , and three edges $\{u, v\}, \{u, z\}, \{v, z\}$; if we assign to the first vertex, say u the color red, then its neighbours v and z should be blue, but, since they are adjacent each other, i.e., there exists the edge $\{v, z\}$, this will not be possible. For a more formal and detailed characterization of bipartite graphs, we refer the reader to [Diestel \(2012\)](#).

Based on the above property, one of the algorithms to test whether a given graph $G = (V, E)$ is bipartite tries to assign different colors to the vertices of G in such a way that each edge will connect vertices having different colors. Without entering into the details of the algorithmic procedure to visit the graph, which is not part of this paper, we will describe the intuitive idea to verify if the graph $G = (V, E)$ is bipartite. The idea of the visit is the following: once you visit a vertex you put all its neighbours in the queue of the vertices that must be visited, so that, at the next step you pop out the next vertex from this queue, visit it, and put its neighbours in the queue. This operation is repeated until the queue is empty, that is, until all the vertices of the graph are visited. Let us denote as c_1 and c_2 the two possible colors to be assigned to a vertex. Initially, none of the vertices of V is colored. First of all, consider the vertex set V of the input graph G , and select a vertex $v \in V$ as a starting point of the visit. Then, color v with c_1 , select the set of its neighbours, color each of them with c_2 , and add them to the queue of vertices to be visited. Now, pop out the first vertex in the queue, say u , select its neighbours, and when considering them, each vertex z can be in one of the three possible situations:

- z is not yet colored, so color it with c_1 (the opposite of the color of u) and put it into the queue of the vertices to be visited;
- z is colored with c_1 , that means that it has been already visited and its color agrees with that of u , so the visit continues (i.e., since u and z are adjacent they must have different colors);
- z is colored with c_2 , that means that it has been already visited but its color does not agree with that of u , and so the visit ends denoting the fact that the graph is not bipartite.

This latter case model the fact that an edge $\{u, z\}$ connects two vertices u and z having the same color, violating the property of bipartite graphs. This situation results from the fact that, during the visit, one of vertices adjacent to u and one of the vertices adjacent to z was previously colored with the other color. If the visit of the graph with the vertex coloring ends without entering in the third case, then the graph $G = (V, E)$ is bipartite, and the two subset of vertices can be obtained based on the two colors assigned during the visit.

It is important to notice that the previously described procedure to check whether a given graph is bipartite does not depend on the choice of the initial vertex of the visit.

Finally, we would like to point out that, although simple, this is a good example of algorithmic procedure designed to solve a specific problem on graphs. Formal details will require the introduction of different concepts and properties that are not part of this article.

Conclusions

Graphs are very important mathematical concepts that are employed in several different fields and so, due to their importance, several properties and theorems have been developed. Moreover, thanks also to their intuitive and easy-to-understand structure, they are often used to model biological networks, like protein-protein interaction networks, gene regulatory networks, or metabolic networks. In addition to systems biology, also bioinformatics takes advantage of graph structures, both to model specific phenomena, like the alternative splicing events occurring in an expressed gene, or to represent specific data structures in the computational procedures designed to solve specific problems. In this latter case, graphs play a fundamental role, especially in guaranteeing the efficiency of the implemented procedure. As an example, one could think at the problem of assembling genomic sequences starting from a set of Next-Generation Sequencing reads, which is usually composed of millions and even billions of short, and also erroneous, short (sub)strings of the sequenced genome. In order to reconstruct the original sequence, it is necessary to deal with this huge amount of information, but, thanks also to the use of graphs in representing the strings (which are usually the so called k -mers), the overall process can be run on a workstation in a quite fast time.

Although these are only a small number of the examples that highlight the importance of graphs in systems biology and bioinformatics, it is quite easy to guess that graphs can be found in many problems. For this reason, a good knowledge of them is fundamental and could be very helpful in doing specific studies or when facing many biological problems.

This article is intended to be an introductory review of the basic concepts about graphs, which could be useful for those that are approaching graphs for the first time. Here, we started with the definition of graphs and we introduced the notions of vertex and edge, adjacency and incidence of vertices, and we also highlighted the difference between directed and undirected graphs. Starting from this point, we explained the meaning of subgraphs of a given graph, induced by a subset of its vertices, and of weighted graphs, both the node- and edge-weighted ones. Then, we introduced two type of graphs: bipartite graphs, in which the set of vertices can be partitioned into two subsets so that there is no edge connecting two vertices in the same subset, and multigraphs, in which there is the possibility of having multiple edges connecting the same pair of vertices. Moreover, due their relevance in different applications, we focused our attention on bipartite graphs by describing a procedure to check whether a given graph is bipartite. Finally, we explained two possible representations of graphs, which are usually adopted by the computational methods using them. The first one is the adjacency lists of the vertices, in which for each vertex there is a list of its neighbours, while the second one is the adjacency matrix in which each cell correspond to a pair of vertices, and there is a 1 value if the corresponding

edge exists, and 0 otherwise. We also highlighted advantages and disadvantages of both the representations, and their extension to weighted graphs.

Introduction

A graph is a mathematical structure that represents relationships (the edges) between elements of a domain (the nodes) in a very intuitive way. In particular, a graph can be represented as a set of nodes, corresponding to the elements, and edges connecting pairs of nodes, representing the fact that two connected nodes have a relation. Taking advantage of its formal definition, several properties and notions have been defined in literature during the years, contributing to the widespread diffusion of graphs in different fields such as physics, computer science, and biology. Strictly related to this latter research area, those fields that involve specific computational aspects, such as bioinformatics and systems biology, make use of graphs in many different applications and studies.

In the context of Next Generation Sequencing consider, for example, the problem of reconstructing the original sequence starting from a huge set of reads, corresponding to substring obtained through a sequencing process. To solve this problems, the majority of the bioinformatic approaches use a graph to represent the input reads, which are usually connected based on their sequence overlap, and tries to assemble them (see Gnerre *et al.*, (2011); Zerbino and Birney (2008) for some examples). Although they vary in the type of adopted graph and in the technique used to reconstruct the sequence, the cores of the methods rely on basic notions coming from graph theory. In fact, several studies have been proposed in literature, ranging from the more theoretical ones (see Beerenwinkel *et al.*, 2015) to more applicative techniques (see Pertea *et al.*, 2015).

On the other hand, graphs are also used to directly model specific biological phenomena on which, then, analysis is performed in order to obtain relevant results. Examples of these applications are the metabolic networks, in which the biochemical reactions of a specific organism are analyzed to extract the most relevant pathways (see Kanehisa *et al.*, 2010; Feist *et al.*, 2009) or the protein-protein interaction networks, in which proteins are connected to each other based on their interactions within a cell or in a specific organism (see Rual *et al.*, 2005).

Due to the high importance of graphs, in this work we will present some basic properties and definitions that are fundamental for a good understanding of this mathematical structure. More precisely, we will start by recalling some basic definitions and then we will describe some notions related to the concept of node degree for undirected graphs. We will also refine this definition for directed graphs for which we can distinguish between in- and out-degree. Starting from this property, we will introduce the notion of k -regular graph and of complete graph, and we will highlight some properties and case studies involving this latter kind of graphs. After that, we will focus on the density measure by giving its definition on both directed and undirected graphs and, finally, based on this measure we will describe two kind of graphs, namely dense (highly connected) and sparse (poorly connected).

Background

Before introducing the main concepts of this work, let us recall some basic notions on graphs. A graph is usually defined as $G=(V,E)$, in which V represents the set of vertices, while E is the set of edges or arcs between pairs of vertices. More precisely, if G is an undirected graph, then the elements of E are usually called edges and are denoted as unordered pairs $\{u,v\} \in E$, with $u,v \in V$. In this case, since there is no orientation associated with the edges, they are sets of two vertices of V , and consequently $\{u,v\} = \{v,u\}$. On the other hand, if G is a directed graph, then the elements of E are usually called arcs and are denoted as ordered pairs of vertices $(u,v) \in E$, with $u,v \in V$. In this case the arc (u,v) is oriented from vertex u to vertex v , and as a consequence $(u,v) \neq (v,u)$, since (u,v) and (v,u) represent two distinct arcs.

Moreover, given an edge $e \in E$, with $e = \{u,v\}$, the vertices u and v are said to be adjacent or neighbor vertices, and are incident on e . Again, if G is an undirected graph, the edge $e = \{u,v\}$ is usually said to be incident on both vertices u and v , whereas if G is a directed graph, then the arc $e = (u,v)$ is said to be incident from (or leaving) vertex u and incident to (or entering) vertex v .

Now, let us consider an undirected graph $G=(V,E)$. The *degree* of a vertex corresponds to the number of edges incident on it. The degree of a vertex $v \in V$ is usually denoted as $\deg(v)$ and can be formally defined as the cardinality of the set $\{\{v,u\} \in E : u \in V\}$. A vertex with degree equals to 0 is said to be *isolated*, since it has no connections with the other vertices of the graph. As an example, consider the graph in Fig. 1(a): the vertex u has degree 3, while the vertex x is isolated.

Let us now consider a directed graph $G=(V,E)$. In a directed graph, for each vertex it is possible to consider three different degrees: *in-degree*, *out-degree*, and *degree*. The in-degree of a vertex $v \in V$, denoted as $\deg^-(v)$, is the number of edges incident to v and, formally, it corresponds to the cardinality of the set $\{\{u,v\} \in E : u \in V\}$. The out-degree of a vertex $v \in V$, denoted as $\deg^+(v)$, is the number of edges incident from v and, formally, it corresponds to the cardinality of the set $\{\{v,u\} \in E : u \in V\}$. Finally, the degree of a vertex $v \in V$, denoted in the same way as for undirected graphs as $\deg(v)$, is equal to its in-degree plus its out-degree, that is, $\deg(v) = \deg^-(v) + \deg^+(v)$. Starting from the previous definitions, in a directed graph, a vertex v can be classified as:

- isolated vertex, if $\deg(v)=0$ (vertex x in Fig. 1(b));
- source vertex, if $\deg^-(v)=0$ (vertex u in Fig. 1(b));
- sink vertex, if $\deg^+(v)=0$ (vertex y in Fig. 1(b));
- internal vertex, if $\deg^-(v) \neq 0$ and $\deg^+(v) \neq 0$ (vertex w in Fig. 1(b)).

Fig. 1 In (a) an example of undirected graph is shown. In this example vertices u, v, w, y have degree 3, 2, 1, 2, respectively. On the other hand, in (b) an example of directed graph is reported. Here, vertex u has in-degree 0 and out-degree 3, while vertex y has in-degree 3 and out-degree 0. The other two vertices v and w have in-degree 2 and out-degree 2. In both the graphs vertex x has degree 0.

The node degree is a fundamental concept, since it is exploited in several different biological applications, and can be used to analyze biological networks. As an example, in Piraveenan *et al.* (2012) new measures are defined to assess the tendency of a node to connect with other nodes that have similar degree, extending the previously defined notion of “assortativity”. Similarly, in Milenković *et al.* (2011) new measures based on the degree of vertices are introduced to identify the most relevant genes in a protein-protein interaction network. In fact, as pointed out in Ideker and Sharan (2008), when studying diseases, genes that play an important role have a high number of connections in the protein-protein interaction network. In addition, it has been shown in Dyer *et al.* (2008) that the majority of the pathogens that are viral and bacterial have the tendency to interact with proteins having a high-degree, or with those that are central in many paths of the network.

In addition to the aforementioned examples in which the concept of node degree plays a central role, there are other bioinformatic applications that take advantage of it. More precisely, one of the ways in which graphs are used, is for representing the input reads obtained with a sequencing process. In this context, and in particular in studies involving the analysis of the DNA of specific bacteria having circular chromosomes, one of the goals is to reconstruct this sequence by assembling the input reads (Blattner *et al.*, 1997; Loman *et al.*, 2015). This is usually done by taking advantage of the overlap among them, but, mainly due to errors in the input sequence, the solution of this problem is not so straightforward. For a more complete introduction on the analysis of Next-Generation Sequencing data for bacterial genomes, we refer the reader to Edwards and Holt (2013). From a computational point of view, this problem corresponds to the that of finding a circular path in the graph that passes through all the edges. Although we do not formally define these concepts, the idea is that we want to find a way in the graph to return to the starting point, by traversing all the edges the minimum number of times. Recalling the assembly problem, this circular path will correspond to the assembled (circular) genome, obtained by merging the overlapping reads found along the path. The variant of the problem in which we want to pass through each edge only once, is called *Eulerian walk*, and it has a solution only if all the vertices in the graph have an even degree. Moreover, for directed graphs, other conditions for the existence of an Eulerian walk are that: (i) at most one vertex v has $\deg^+(v) - \deg^-(v) = 1$, (ii) at most one vertex u has $\deg^-(u) - \deg^+(u) = 1$, and (iii) all the other vertices have equal in-degree and out-degree. Once assessed its existence, the walk can be reconstructed by exploiting some algorithms proposed in literature (Fleury, 1883; Fleischer, 1991).

A very well-known type of graphs, which are involved in different studies, are the so called regular graphs. Given a graph $G=(V,E)$, if all its vertices have the same degree k , then G is said to be k -regular. One of the examples of these kind of graphs are the lattices, in which vertices can be thought as disposed as a (usually regular) grid, and each vertex is connected with its grid neighbours, that is, it has 4 edges. To be more precise, in order to be regular a graph, the lattice must connect the vertices on the border, that is, those in first/last column/row with the corresponding ones in the last/first column/row, respectively. This graph is called *toroidal*.

Starting from the previously introduced concepts, we are now able to define the concept of *complete graphs*. More precisely, an undirected graph $G=(V,E)$ is complete if for every pair of distinct vertices in V , there exists an edge in E connecting them. Formally, for each pair of vertices $u, v \in V$ such that $u \neq v$, then $\{u, v\} \in E$. From this definition it is easy to observe that a complete graph $G=(V,E)$ having $|V|$ vertices has exactly $\frac{|V|(|V|-1)}{2}$ edges. Since in a complete graph there exists an edge between every pair of vertices, that number is the maximum number of possible (distinct) edges in a graph. Fig. 2 shows some representations of complete undirected graphs having vertex sets of sizes ranging from 2 to 9.

The definition of complete graph we introduced for undirected graphs, can be extended also to the directed ones. In particular, in a directed complete graph $G=(V,E)$, for every pair of distinct vertices $u, v \in V$, that is $u \neq v$, there exist two arcs connecting them, i. e. $(u, v) \in E$ and $(v, u) \in E$. In this case, a complete directed graph $G=(V,E)$ having $|V|$ vertices has $|V|(|V|-1)$ arcs. As an example, Fig. 3 shows some possible representations of complete directed graphs having vertex sets of sizes ranging from 2 to 5.

Complete graphs, which are usually referred to as *cliques*, are a very important type of graphs, and several problems are focused on the identification of complete (and usually maximal) subgraphs. Let us recall the notion of subgraph. Given a graph $G=(V,E)$ and a subset $V' \subseteq V$ of vertices of V , then the subgraph of G induced by V' is the graph $G'=(V',E')$, where E' is the set of edges incident in the vertices of V' . More formally, we say that E' is the set $\{\{u, v\} \in E : u \in V' \wedge v \in V'\}$. A very important problem related to the concept of complete (sub)graphs asks to extract, from a given graph, the maximal clique, that is, the maximum subset of vertices $V' \subseteq V$ for which the induced subgraph $G'=(V',E')$ is a clique.

Fig. 2 Examples of complete undirected graphs, having the number of vertices ranging from 2 (upper leftmost graph) to 9 (lower rightmost graph).

Fig. 3 Examples of complete directed graphs, having the number of vertices ranging from 2 (leftmost graph) to 5 (rightmost graph).

This latter problem has several applications in both systems biology and bioinformatics. More precisely, one of the main problems for which protein-protein interaction networks are adopted is the identification of the complete set of interactions among the proteins in a cell. In this context, cliques represent a subset of vertices, that is proteins, having pairwise connections allowing the possibility to identify the interactions among a great number of proteins (Yu *et al.*, 2006). Other examples of maximal complete subgraph identifications are in gene network analyses, in which cliques represent local clusters, containing proteins of likely similar biological function (Ciriello *et al.*, 2012) or when studying the effect of microRNA with cancer networks (Volinia *et al.*, 2010). Moreover, in bioinformatics complete subgraphs can be used to reconstruct the structure of a viral quasispecies from Next-Generation Sequencing data obtained from a set of mixed virus samples (Tpfer *et al.*, 2014) or to compute the distance between tree structures, such as those resulting from the folding of RNA molecules (Fukagawa *et al.*, 2011).

Another notion that is strictly connected with that of complete graphs is the *complete bipartite graph*, also called *biclique*. More precisely, a bipartite graph $G=(V,E)$ in which $V=V_1 \cup V_2$, $V_1 \cap V_2 = \emptyset$, and no edge connects two vertices of the same subset, is a biclique if for every pair of vertices of the two subsets there exists an edge in E connecting them. Formally, for each $v \in V_1$ and $u \in V_2$, $\{u,v\} \in E$. From this definition it is easy to observe that the number of edges in G is $|V_1| \cdot |V_2|$. Examples of this kind of graph are the so called *stars*, which are complete bipartite graphs in which one of the two subsets is composed of only one vertex.

Methodologies

In this section we will introduce some notions related to the concept of density, which is very useful especially when studying biological networks.

Now, for ease of exposition, in the rest of the section we will consider only graphs $G=(V,E)$ without loops, that is, without edges $\{v,v\}$, with $v \in V$.

The density of a graph $G=(V,E)$, which is usually denoted as δ_G , is a measure to express the relationship between its number of edges and its number of vertices. If G is an undirected graph, the density δ_G can be computed as

$$\frac{2 \cdot |E|}{|V| \cdot (|V| - 1)}$$

since each single edge $\{u,v\} \in E$, with $u \neq v$, ideally represents two different arcs, namely (u,v) and (v,u) .

On the other hand, if G is a directed graph, instead, the density can be computed as

$$\frac{|E|}{|V| \cdot (|V| - 1)}$$

For example, the density of the graph shown in Fig. 1(a) is equal to $8/20=0.4$, while the density of graph shown in Fig. 1(b) is equal to $6/20=0.3$.

Fig. 4 Examples of sparse graphs. In (a) an example of undirected graph having low density ($\delta_G=6/20=0.3$) is shown. In (b) an example of directed graph having low density ($\delta_G=3/20=0.15$) is reported.

Fig. 5 Examples of dense graphs. In (a) an example of undirected graph having high density ($\delta_G=14/20=0.7$) is shown. In (b) an example of directed graph having high density ($\delta_G=12/20=0.6$) is reported.

Based on this measure, it is possible to define two types of graphs. More precisely, a graph $G=(V,E)$ with only a few edges i.e., a graph with low density ($\delta_G \leq 0.5$, or $|E| \ll |V|^2$, or $|E| \approx |V|$) is said to be *sparse*. [Fig. 4\(a\)](#) shows a sparse undirected graph, while [Fig. 3](#) a sparse directed graph.

On the other hand, a graph $G=(V,E)$ with a number of edges close to the maximal number of (possible) edges i.e., a graph with high density ($\delta_G \geq 0.5$, or $|E| \approx |V|^2$) is said to be *dense*. [Fig. 5\(a\)](#) shows a dense undirected graph, while [Fig. 5\(b\)](#) a dense directed graph.

Finally, notice that a complete graph $G=(V,E)$ has density equal to 1, i.e. $\delta_G=1$.

Starting from the previous classification of graphs, based on the density measure, we would like to point out that, the fact that a graph is sparse or dense can influence the way it should be represented. In particular, although it strictly depends on the specific application and also on the operations that must be performed on the graph, it is possible to prefer different representations for these two kind of graphs. If a graph is sparse then it could be convenient to explicitly store the edges with a set of *adjacency lists* in order to save some space, although each operation (usually) requires to scan through those lists. On the other hand, if a graph is dense, then an *adjacency matrix* representation could be more suitable since it allows to store all the possible edges (that are $|V| \times |V|$), also guaranteeing good performance on some operations (like to check the existence of an edge). More details on these aspects can be found in [Cormen et al. \(2009\)](#).

As for complete graphs, also for these two kind of density-based graphs, in most of the studies and the applications, the interest is in identifying subgraphs that are dense (or sparse, depending on the final goal). In fact, considering for example the previously mentioned biological networks and in particular the protein-protein interaction ones, although the entire network could be sparse, there could exist some dense subgraphs which constitute the most relevant interactions. Several approaches have been proposed to solve this problem, exploiting different techniques such as clustering and subgraphs enumerations (see [Adamcsek et al., 2006](#); [Nepusz et al., 2012](#)), or data mining algorithms (see [Bahmani et al., 2012](#); [Tsourakakis et al., 2013](#)).

Conclusions

Thanks to the combination of an intuitive representation of relations between elements, and a formal mathematical structure, graphs are used in many fields, ranging from physics to compute science, and from mathematics to biology. As a consequence of this fact, they play a central role in several studies, especially in areas like systems biology and bioinformatics in which different properties and methods are exploited to efficiently solve different problems. These notions, although very intuitive and easy to understand, constitute a strong basis for a better understanding of graph structures, and are fundamental to develop new methods and to perform specific studies.

In this work we presented the basic properties of graphs and, in particular, we explained the concept of node degree, starting from its definition with respect to both directed and undirected graphs. Based on this definition, we also introduced two types of graphs, that are the so called k -regular ones and the complete graphs. Moreover, when explaining these concepts we provided some examples of their applications in different studies present in literature, introducing also some property arising from them.

After that, we focused our attention on a very important measure that has been defined on graphs, that is, the density. We provided the formal definition, on both directed and undirected graphs, and we described two types of graphs that it is possible to identify, based on this latter measure: dense and sparse graphs. More precisely, the former ones are graphs having a density greater than 0.5, that correspond to fact of having a high number of edges, while the latter ones are graphs having density smaller than 0.5, that correspond to the fact of having a small number of edges. Finally, we gave some additional notions on these types of graphs and we provided some examples.

Introduction

Graphs (or networks) have played a relevant role in computational biology in the last few years. Several biological problems have been modeled using graphs, from protein interaction networks (Spirin and Mirny, 2003; Scott *et al.*, 2006) to the representation of the relations among orthologous and paralogous genes (Hellmuth *et al.*, 2014; Lafond *et al.*, 2016).

In this contribution we will focus on the main concepts related to graph isomorphism, graph traversal and graph/network measures. First, we introduce in Section Background/Fundamentals some concepts related to graph traversals (paths, walks, cycles, circuits), graph connection properties and partition (diameter, connected components and strongly connected components), and graph isomorphism. In Section Methodologies, we investigate two main measures of a graph/network: network topology measures (average path length, diameter, cluster coefficient, degree distribution) and centrality measures (degree centrality, closeness centrality, betweenness centrality, eigenvector centrality). We then introduce the methods for the detection of recurrent subgraphs (motifs) inside a network and the related subgraph isomorphism problem. We present in Section Illustrative Examples some examples of application of these measures and concepts in computational biology.

Background/Fundamentals

In what follows we denote by $G=(V, E)$ an undirected graph, where V is the set of vertices and E is the set of (undirected) edges, and by $D=(V, A)$ a directed graph (or digraph), where V is the set of vertices and A is the set of (directed) arcs. We represent an edge of $G=(V, E)$ between vertices $u, v \in V$ as $\{u, v\}$, while we denote a directed arc of $D=(V, A)$ between vertices $u, v \in V$ as (u, v) . Given a set S , we denote by $|S|$ the size or cardinality of S .

Given a vertex v of G , we denote by $N(v)$ the set of vertices adjacent to v , or the neighborhood of v . Formally:

$$N(v) = \{u : \{u, v\} \in E\}$$

For example in Fig. 1, $N(v_1) = \{v_2, v_3\}$

In a directed graph $D=(V, A)$, given a vertex $v \in V$, we denoted by $N_{in}(v)$ (by $N_{out}(v)$, respectively) the in-neighborhood (the out-neighborhood, respectively) of v , that is the set of vertices that have an incoming arc in v (an outgoing arc from v , respectively). Formally:

$$N_{in}(v) = \{u : (u, v) \in A\}$$

$$N_{out}(v) = \{u : (v, u) \in A\}$$

Consider Fig. 2, $N_{in}(v_3) = \{v_2, v_5\}$, while $N_{out}(v_3) = \{v_1\}$.

Let $V' \subseteq V$, we denote by $G[V']$ the subgraph induced by V' , that is $G[V'] = (V', E')$, where

$$E' = \{\{u, v\} : \{u, v\} \in E, u, v \in V'\}$$

For example, consider Fig. 1. The graph induced by $V' = \{v_1, v_2, v_3\}$ has edges

$$E' = \{\{v_1, v_2\}, \{v_2, v_3\}, \{v_2, v_3\}\}$$

Fig. 1 An undirected graph $G=(V, E)$.

Fig. 2 A directed graph $D=(V, A)$.

Given a graph $G=(V, E)$ (a directed graph $D=(V, A)$, respectively), a *path* Π in G (in D , respectively) is a sequence of distinct vertices $v_{\Pi(0)}, v_{\Pi(1)}, \dots, v_{\Pi(h)}$, such that $\{v_{\Pi(j)}, v_{\Pi(j+1)}\} \in E$, for each j with $0 \leq j \leq h-1$ ($\{v_{\Pi(j)}, v_{\Pi(j+1)}\} \in A$, for each j with $0 \leq j \leq h-1$, respectively). The length of a path $\Pi=(v_{\Pi(0)}, v_{\Pi(1)}, \dots, v_{\Pi(h)})$ is h , that is the number of vertices that belong to the path minus one.

A *walk* in a graph $G=(V, E)$ (in a directed graph $D=(V, A)$, respectively) is a sequence Π of vertices $v_{\Pi(0)}, v_{\Pi(1)}, \dots, v_{\Pi(h)}$, such that $\{v_{\Pi(j)}, v_{\Pi(j+1)}\} \in E$, for each j with $0 \leq j \leq h-1$ ($\{v_{\Pi(j)}, v_{\Pi(j+1)}\} \in A$, for each j with $0 \leq j \leq h-1$, respectively). As for paths, the length of a walk Π' is the number of vertices in Π' that belong to the walk minus one.

Notice that the vertices in a path Π must be distinct, while vertices that belong to a walk are not necessarily distinct. Consider graph G in Fig. 1; $\Pi=v_1, v_2, v_4, v_6$ is a path between v_1 and v_6 of length 3 in G . $\Pi'=v_1, v_2, v_4, v_5, v_6, v_4$ is a walk in G from v_1 to v_4 of length 5, but is not a path, since vertex v_4 appears twice in Π' .

Notice that $\Pi=v_1, v_2, v_4, v_6$ is not a path in D of Fig. 2, since (v_1, v_4) and (v_4, v_6) are arcs of D , while (v_2, v_4) is not an arc of D (notice that (v_4, v_2) is an arc of D).

A walk $\Pi=v_{\Pi(0)}, v_{\Pi(1)}, \dots, v_{\Pi(h)}$ in a graph G (a digraph D , respectively) is called a *cycle* if each vertex in Π is distinct except for the first and the last vertex, that is $v_{\Pi(0)}=v_{\Pi(h)}$. A walk $\Pi=v_{\Pi(0)}, v_{\Pi(1)}, \dots, v_{\Pi(h)}$ is called a *circuit* if the first and the last vertex are identical, that is $v_{\Pi(0)}=v_{\Pi(h)}$. The length of a cycle and of a circuit are defined as for the length of a walk and of a circuit.

Similarly to the difference between path and walk, notice that in a cycle all the vertices except for the first and the last are distinct, while this may not be the case for a circuit. Consider graph G in Fig. 1, $C=v_1, v_2, v_3, v_1$ is a cycle (and also a circuit) in G having length 3. Consider $C'=v_1, v_2, v_4, v_5, v_2, v_3, v_1$; C' is a circuit in G having length 6, but is not a cycle, since vertex v_2 has two occurrences in C' .

Given two vertices u, v of a graph $G=(V, E)$ (of a directed graph $D=(V, A)$), the *distance* $d_G(u, v)$ between u and v in G (the distance $d_D(u, v)$ between u and v in D , respectively), is the length of the shortest path between u and v . Vertices v_1 and v_2 in graph G of Fig. 1 have distance 1 since they are adjacent; vertices v_1 and v_6 have distance 2, since $\Pi=v_1, v_5, v_6$ is the unique shortest path between v_1 and v_6 in G and Π has length 2. Notice that several shortest paths may exist between two vertices and that while d_G is symmetric, that is $d_G(u, v)=d_G(v, u)$, this is not the case for d_D , that is $d_D(u, v)$ may be different from $d_D(v, u)$. For example in the directed graph D of Fig. 2, $d_D(v_1, v_2)=1$, while $d_D(v_2, v_1)=2$. When there is no path from u to v , the distance usually has value $+\infty$.

A measure that has been widely used to study graph and network is the *diameter*. The diameter of an undirected graph $G=(V, E)$ (a directed graph D) is the maximum distance between any pair of vertices of G (of $D=(V, A)$, respectively). Formally,

$$\text{diam}(G) = \max_{u, v \in V} d_G(u, v)$$

$$\text{diam}(D) = \max_{u, v \in V} d_D(u, v)$$

Graph G in Fig. 1 has diameter 2, since $d_G(v_1, v_6)=2$ and the distance between any other pair of vertices in G is at most 2.

An undirected graph $G=(V, E)$ is called a *clique* (or a complete graph), when for each $u, v \in V$, $\{u, v\} \in E$, that is each pair of vertices in V is connected by an edge. A subgraph $G[V']$ of $G=(V, E)$, where $V' \subseteq V$, is called a clique of G when for each $u, v \in V'$, $\{u, v\} \in E$. When $G[V']$ is a clique, we say that V' induces a clique in G . The size of a clique $G[V']$ is $|V'|$.

A clique $G[V']$ of $G=(V, E)$ is called *maximal* if there is no vertex $u \in V/V'$ such that $\{u, v\} \in E$ for each vertex $v \in V'$. Intuitively, a clique $G[V']$ is maximal if it cannot be extended by adding some vertex to V' , that is there is no vertex of $v \in V/V'$ such that $\{v, u\} \in E$ for each $u \in V'$. A *maximum clique* $G[V']$ of $G=(V, E)$, with $V' \subseteq V$, is a clique of G having maximum size, that is there is no set W , with $W \subseteq V$ and $W \neq V'$, such that $G[W]$ is a clique and $|W| > |V'|$. Notice that a maximum is also a maximal clique, while a maximal clique may not be a maximum one. A concept related to a clique is that of *independent set*. An undirected graph $G=(V, E)$ is an independent set if $E=\emptyset$. A subgraph $G[V']$ of $G=(V, E)$, with $V' \subseteq V$, is an independent set if $\{u, v\} \notin E$, for each $u, v \in V'$. Notice that $G=(V, E)$ is an independent set if and only if the complement of G , $\bar{G}=(V, \bar{E})$, is a clique, where $\bar{E}=\{\{u, v\} : \{u, v\} \notin E\}$. As for cliques, we can define maximal and maximum independent set.

Consider a graph G in Fig. 1. The subgraphs induced by $\{v_1, v_2, v_3\}$, $\{v_1, v_2, v_3, v_5\}$, $\{v_4, v_5, v_6\}$ are all cliques of G . However notice that $\{v_1, v_2, v_3\}$ does not induce a maximal clique, since $\{v_1, v_2, v_3\} \subset \{v_1, v_2, v_3, v_5\}$. $G[\{v_4, v_5, v_6\}]$ is a maximal clique, but not a maximum clique, since it contains three vertices, while $G[\{v_1, v_2, v_3, v_5\}]$ contains four vertices; $G[\{v_1, v_2, v_3, v_5\}]$ is a maximum clique in G , as there is no clique of size 5 in G .

The sets $\{v_1, v_6\}$ and $\{v_3, v_4\}$ are two independent sets in G , since $\{v_1, v_6\} \cap E = \emptyset$ and $\{v_3, v_4\} \cap E = \emptyset$. They are both maximum independent sets of G .

A fundamental concept in graph theory is that of *connected component* of an undirected graph.

Definition 2.1: Given an undirected graph $G=(V, E)$, a *connected component* of G is a graph $G[V']$ induced by a maximal set $V' \subseteq V$ such that for each $v_1, v_2 \in V'$, there exists a path in G' from v_1 to v_2 .

Consider the graph G in Fig. 3. G contains two connected components: $G[\{v_1, v_2, v_3, v_4, v_5, v_6\}]$ and $G[\{v_7, v_8, v_9\}]$.

In directed graphs, the orientation of arcs leads to a different concept, that of *strongly connected component*.

Definition 2.2: Given a directed graph $D=(V, A)$, a *strongly connected component* is a graph $D[V']$ induced by a maximal set $V' \subseteq V$ such that for each pair (v_1, v_2) of vertices in $D[V']$, there exists a directed path $\Pi(v_1, v_2)$ in $D[V']$.

Consider the graph D in Fig. 4. D contains two strongly connected components: the strongly connected component induced by $\{v_1, v_2, v_3\}$ and the strongly connected component induced by $\{v_4, v_5, v_6\}$. Notice that if we ignore arc orientation, D is connected.

An interesting properties of directed graphs is that a directed graph $D=(V, A)$ can be decomposed in a second directed graph called *component directed graph* $D_{SCC}(D)=(V_{SCC}, A_{SCC})$, where the vertices in V_{SCC} correspond to strongly connected components of D and there is an arc (v_a, v_b) in A_{SCC} if and only if there is an arc in D from a vertex in the strong connected component associated with v_a to a vertex in the strong connected component associated with v_b . Notice that D_{SCC} is a directed acyclic graph.

Consider the directed graph $D=(V, A)$ in Fig. 4. The directed graph contains three directed components induced by vertices $\{v_1, v_2, v_3\}$, $\{v_4, v_5, v_6\}$ and $\{v_7\}$, respectively. The corresponding component directed graph D_{SCC} contains three vertices, corresponding to the three strongly connected components of D , and two arcs.

A problem widely investigated in computer science and graph theory, with application in the analysis of biological networks, is *graph isomorphism*. Graph isomorphism defines a bijection between the vertices of two given graphs (a similar definition can be given for isomorphism between directed graphs).

Fig. 3 A graph $G=(V, E)$ with two connected components.

Fig. 4 A directed graph $D=(V, A)$ with three connected components (left) and the corresponding component directed graph D_{SCC} (right). Notice that the vertices of D_{SCC} are named with the vertices in the corresponding strongly connected components of D .

Fig. 5 Two isomorphic graphs G_1 and G_2 .

Definition 2.3: Given two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, a graph isomorphism is a bijective function $f: V_1 \rightarrow V_2$, such that $\{u, v\} \in E_1$ if and only if $\{f(u), f(v)\} \in E_2$.

Consider the two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ represented in Fig. 5. The two graphs are isomorphic, since it is possible to define a bijection $f: V_1 \rightarrow V_2$ defined as follows: $f(v_1) = w_4$, $f(v_2) = w_3$, $f(v_3) = w_5$, $f(v_4) = w_2$, $f(v_5) = w_1$. Consider for example $\{v_1, v_2\} \in E_1$; it holds that $\{f(v_1), f(v_2)\} = \{w_4, w_3\} \in E_2$. It can be checked by direct inspection that indeed f defines an isomorphism between G_1 and G_2 .

Methodologies

In this section, we consider three main topics related to the analysis of a graph: network topology measures (applied to study to the global structure of a graph/network), centrality measures (applied to study the relevance of a specific vertex inside a network) and detection of network motifs (identification of relevant part of a graph/network).

Network Topology Measures

Several measures have been introduced to understand topological properties of a network. Here we introduce three well-known and applied measures: average path length, cluster coefficient, degree distribution.

The *average path length* of a graph has been introduced to measure the average distance between vertices of the graph, to characterize, for example, the information flow inside a network. Given an undirected graph $G = (V, E)$, the *average path length* $av(G)$ is defined as

$$av(G) = \frac{1}{|V|(|V| - 1)} \sum_{u, v \in V, u \neq v} d_G(u, v)$$

where we assume that $d_G(u, v) = 0$ when there is no path from u to v . A similar definition can be given for directed graphs.

Consider graph G in Fig. 1. Then

$$av(G) = \frac{40}{30}$$

The value of the *average path length* of a graph is related to the *small-world phenomenon*. In several analyzed graphs, like the World Wide Web, the reaction graph of Escherichia coli or the network representing the neural structure of Caenorhabditis elegans, the average path length is bounded with respect to the size of the graph (Albert and Barabási, 2002). Given a graph having n vertices, a graph that follows the small-world phenomenon has an average path length of value $O(\log n)$ (Watts and Strogatz, 1998).

Cluster coefficient has been introduced to measure the degree of transitivity in graph edges. Two measures have been introduced in this context: *global cluster coefficient* and *local cluster coefficient*. Given a graph $G = (V, E)$, define a triplet in G as a connected graph induced by three vertices. Denote by $\#_{Tr}$ the number of triplets in G , and by $\#_{CompTr}$ the number of triplets in G that are cliques (of size 3). The *global cluster coefficient* C_{Global} is defined as:

$$C_{Global} = \frac{3\#_{CompTr}}{\#_{Tr}}$$

Notice that $\#_{CompTr}$ is multiplied by three, as each clique of size three induces three triplets.

The *local cluster coefficient* $C_{local}(v)$ of a vertex $v \in V$ is defined as:

$$C_{local} = \frac{2|\{\{u, w\} : u, v \in N(v)\}|}{|N(v)|(|N(v)| - 1)}$$

The global cluster coefficient has been introduced to measure the degree of transitivity of the whole given graph, while the local degree clustering measure the degree of transitivity only in the neighborhood of a specific vertex v .

Degree distribution measures how many vertices of a graph have a given degree $k \geq 0$. In directed graphs, this measures is usually applied to the in-degree of the graph. Degree distribution has been introduced to understand the structure of networks and it is used for example to detect whether there are vertices that are particularly relevant for a network, like hubs. Hubs are vertices of a network that have a huge degree, when compared to the size of the network. In random-graph models degree distribution follows

a Gaussian law, and no hub is present in networks built according to these models. In scale-free network models degree distribution follows a power-law, and hubs are present in networks built according to these models. Several biological networks, for example metabolic networks, have been explained using the scale-free model (Jeong *et al.*, 2000).

Centrality Measures

Centrality measures have been introduced to measure the relevance of a specific vertex of a graph. Several measures have been introduced, based on different properties. We review some of the most relevant centrality measures:

- Degree centrality
- Closeness centrality
- Betweenness centrality
- Eigenvector centrality

Degree centrality of a vertex v is equal to the degree of v . The degree centrality measures the capability of establishing relationships of a given vertex. Consider the graph G in Fig. 1; then the vertex having maximum degree centrality is v_5 , since it has degree centrality 5, while v_2 has degree centrality 4 and v_1, v_3 have degree centrality 3.

Closeness centrality of a vertex v , in a connected graph, is defined as the average distance (length of a shortest path) between v and all other vertices of the graph. Central vertices are those closer to other vertices of the network. Consider the graph G in Fig. 1; then the vertex having maximum closeness centrality is v_5 , since v_5 has closeness centrality 5; v_5 is indeed adjacent to any other vertex of G . Vertex v_2 has closeness centrality 6, since v_2 has distance 1 from v_1, v_3, v_4, v_5 and has distance 2 from v_6 .

Betweenness centrality of a node v is defined as the number of shortest paths between other vertices than v that contain v . Betweenness centrality is used to measure the relevance of a vertex in the connecting vertices of a graph. Consider the graph G in Fig. 1. Then the vertex having maximum betweenness centrality is v_5 , since v_5 has degree centrality 4: a shortest path between v_6 and v_1, v_6 and v_2, v_6 and v_3 passes through v_5 ; a shortest path between v_3 and v_4 passes through v_5 . The betweenness centrality of v_1, v_3 and v_6 is 0, as no shortest path passes through any of these vertices. The betweenness centrality of v_2 is 2, since a shortest path between v_1 (v_3 , respectively) and v_4 passes through v_2 . Finally, the betweenness centrality of v_4 is 1, since a shortest path between v_2 and v_6 passes through v_4 .

Eigenvector centrality measures the influence of a vertex in a graph. Eigenvector centrality of a vertex v is proportional to eigenvector centrality of the vertices in $N(v)$. Formally

$$Mc = \lambda c$$

where M is adjacency matrix of graph G , c is an eigenvector of matrix M and λ is a constant. Informally, the eigenvector centrality value of a vertex v depends on the eigenvector centrality values of vertices in $N(v)$, while the eigenvector centrality value of v influences that of vertices in $N(v)$. A variant of eigenvector centrality is page rank, a centrality measure well-known due to its application in Web search (for more details on page rank see Langville and Meyer (2003)).

Motif Detection

The identification of motifs inside a network is a fundamental task in several contexts, from biological to social networks. A *motif* is a graph (also called a pattern). An *occurrence* of a motif G_1 in a graph $G=(V, E)$ is a subgraph $G[V']$, for some $V' \subseteq V$, which is isomorphic to G_1 . Notice that finding an occurrence of a motif in a graph is the *subgraph isomorphism problem*. Usually, methods look for motifs that have a statistically significant number of occurrences in a graph. Identifying network motifs is a relevant problem, as the presence of a motif is considered to be related to functional properties of biological systems.

Another approach similar to graph motif is based on the identification of highly cohesive subgraphs. The most known problem is that computing clique of maximum size. However, other approaches have been recently proposed based on the relaxation of some constraints of the clique definition, leading to the general concept of *clique-relaxation* (Komusiewicz, 2016). Clique-relaxation includes degree relaxation, connectivity relaxation, distance relaxation. For example, distance relaxation leads to the definition of s -club: an s -club, for $s \geq 1$, is a set of vertices having at distance at most s . When $s=1$, a 1-club is a clique. However, for $s > 1$, an s -club is not necessarily a clique and the problems of computing a maximum size s -club exhibits different properties from that of computing a maximum size clique.

Analysis and Assessment

In this section we discuss the main complexity results related to graph isomorphism, subgraph isomorphism, maximum clique computation and variants thereof. Observe that a shortest path between two vertices can be computed in polynomial time.

Graph Isomorphism

The graph isomorphism problem is a fundamental problem in computer science with many applications in several fields. The computational complexity of graph isomorphism is a long standing open problem, as it is not known to be in P or not.

The NP-completeness of graph isomorphism would imply the collapsing of the polynomial hierarchy to the second level (Goldreich *et al.*, 1986). A quasipolynomial time algorithm of time complexity $\exp((\log|V|)^{O(1)})$ for the graph isomorphism problem has recently been given in Babai (2016).

Motif Detection

The subgraph isomorphism problem, that is computing whether a graph G_2 is a subgraph of a graph G_1 is an NP-complete problem (Cook, 1971). Computing a maximum clique is a well-known NP-hard problem (Karp, 1972). The approximation complexity of the maximum clique has been investigated, leading to prove that the problem is not approximable within factor $O(|V|^{1-\epsilon})$, assuming $P \neq NP$ (Zuckerman, 2007). As for the parameterized complexity, maximum clique is $W[1]$ -complete (Downey and Fellows, 1995a,b), hence it is unlikely that it admits algorithms of time complexity $O(f(k)|V|)$ for a given graph $G=(V, E)$, where k denotes the size of the clique.

The problem of computing a maximum size s -club of maximum size has been extensively studied, and it is known to be NP-hard (as Max-clique), but fixed-parameter tractable (unlike Max-clique) (Schäfer *et al.*, 2012; Chang *et al.*, 2013).

Illustrative Examples

There several problems related to the computation of paths in a graph, with application in computational biology.

A notable example is the detection of signaling pathways in protein interaction networks (Scott *et al.*, 2006). Protein interactions are represented with a graph, whose vertices represent proteins and whose edges represent interaction. A signal pathway is a chain of interacting proteins. An approach to compute signaling paths is based on the computation of a path of a given length k and exploits the color-coding technique (Alon *et al.*, 1995) for the design of a fixed-parameter tractable algorithm for this problem.

A second example can be found in the representation of the structure of a gene with respect to alternative splicing events. Graph approaches have been proposed to represent the structure of a gene with an acyclic graph, called *isoform graph* (Lacroix *et al.*, 2008) or splicing graph (Beretta *et al.*, 2014). In this directed graph, vertices represent exons (or substrings of exons) and a directed arc represents the fact that two exons are consecutive in a transcript. Then certain paths in these directed graphs are sought to identify transcript.

Motif detection is a fundamental problem in biological network analysis. Motifs related to regulatory functions have been found for example in *Escherichia coli* (Alon, 2007). Clique detection has also been applied in several network analysis problems. A notable example is in the context of protein-protein interaction network, where maximal cliques are identified to discover molecular modules (Spirin and Mirny, 2003).

A concept related to motifs in vertex colored-graphs has been introduced to study properties of metabolic networks (Lacroix *et al.*, 2006; Dondi *et al.*, 2013,2011). In this model a vertex-colored graph $G=(V, E)$ and a multiset M of colors are given. The problem, called colored-motif, asks for a colorful motif in G , that is a subgraph $G[V']$, with $V' \subseteq V$, whose vertices have colors that matches M . The problem is NP-complete, even in restricted cases (for example when the input graph is a tree of bounded degree), but is fixed-parameter tractable (Fellows *et al.*, 2011; Björklund *et al.*, 2016; Pinter *et al.*, 2016).

Closing Remarks

In this contribution we have reviewed some of the most relevant concepts and properties related to graph isomorphism and graph components. We have given definition and examples of the main concepts related to graph traversal and connectivity in a graph. We have considered problems related to subgraph isomorphism and motif detection (maximal clique and maximum clique, clique relaxations). Moreover, we have reviewed two measures that have been widely applied to study graphs: network topology measures (average path length, diameter, cluster coefficient, degree distribution), centralization measures (degree centrality, closeness centrality, betweenness centrality, eigenvector centrality). Finally, we have given some examples of how these concepts and methodologies are applied in computational biology.

Introduction

The design and analysis of algorithms on graphs is a relevant and active area in computer science and discrete mathematics, with several application in different fields, from transport network to social network analysis and computational biology. Since graphs are structure widely applied to model problems in different contexts, the research has focused on the design of efficient algorithms for some natural problems. First, we will consider the problem of traversing and exploring a graph. Two well-known approaches for traversing a graph are depth-first search and breadth-first search, and we will consider different properties of these two search algorithms.

A natural problem when dealing with graphs is the quest for shortest paths between a source vertex and a target vertex. The computation of a shortest path between two vertices of a graph has several applications, from transportation and networking to specific problems in computational biology. We will review three well-known algorithms for computing shortest paths: Dijkstra's algorithm, Bellman–Ford algorithm and Floyd–Warshall algorithm.

A third well-known problem that has been considered in this context is the computation of maximum flow that can be transferred from a source vertex to a target vertex of a graph. We will review the Ford–Fulkerson algorithm and the relation between maximum flow and minimum cut of a graph. The computation of maximum flow and minimum cut have several applications from scheduling to phylogenetics.

Another graph problem that has application in several fields, is the computation of a minimum spanning tree of a graph. The problem has been considered in different contexts, from example networking and clustering. Given a graph, the minimum spanning tree problem ask for a tree that covers all the vertices of a given graph. We will review two well-known algorithms to compute a minimum spanning tree: the Kruskal's algorithm and the Prim's algorithm.

Finally, we will consider a graph problem that has been extensively studied in the last fifty years, the traveling salesman person, and we illustrate an algorithmic technique, known as nearest neighbour, that has been applied to design a heuristic for the traveling salesman person.

First, we introduce in Section Background/Fundamentals some definitions that will be useful in the rest of the paper. Then, in Section Methodologies, we will describe the graph algorithms we consider and in Section Analysis and Assessment we will discuss their time complexity. Finally, in Section Illustrative Examples, we will present some biological applications of the graph algorithms described in Section Methodologies.

Background/Fundamentals

In what follows, we will consider both weighted and unweighted graphs. We will focus mainly on undirected graphs, but most of the algorithms we consider can be extended to directed graphs. Given a graph $G=(V, E)$, a *path* Π in G is a sequence of distinct vertices $s=v_1, v_2, \dots, v_h=t$, having a source vertex s and a target vertex t .

Given a graph $G=(V, E)$, a *spanning tree* of G is a tree $T=(V, E')$ such that $E' \subseteq E$. We recall that a tree is a graph that induces no cycle. A *minimum spanning tree* $T'=(V, E')$ of a weighted graph G is a spanning tree of G that has minimum weight, that is

$$\sum_{\{u,v\} \in E'} w(\{u,v\})$$

is minimum among the spanning tree of G . Here $w: E \rightarrow \mathbb{R}^+ \cup \{0\}$ is the weight function, that associates a non negative value with each edge of G .

A path Π in $G=(V, E)$ is called *hamiltonian* if each vertex of V belongs to Π , that is each vertex of V is visited exactly once by Π . This definition can be extended to cycles, thus leading to the definition of hamiltonian cycles. The path $\Pi = v_1, v_3, v_6, v_4, v_5, v_2$ in the graph G of Fig. 1(a) is a hamiltonian path; the cycle $C = v_1, v_3, v_6, v_4, v_5, v_2, v_1$ is a hamiltonian cycle in G .

Methodologies

In this section we review some of the most relevant and studied graph algorithms. We start with depth-first search and breadth-first search traversal of a graph.

Breadth-First Search and Depth-First Search

Breadth-First Search (BFS) and Depth-First Search (DFS) are two basic algorithms for traversing a graph. In both algorithms, we assume that we are given an unweighted and undirected graph $G=(V, E)$, although the algorithm can be generalized to weighted

and directed graphs. Moreover, we consider a vertex $s \in V$, called the *source*, and we want to traverse every edge of G . Vertices of the graph can be in two possible states during the execution of breadth-first search and depth-first search: *undiscovered*, before the visit finds the vertex, *discovered*, when the algorithm has visited the vertex but some of the edges incident in it have not been considered, and *explored* once the vertex and each edge incident in it have been visited. Notice that when the two algorithms start, each vertex of G is unexplored.

We start presenting breadth-first search. Breadth-first search starts from vertex s and marks s as discovered, and visit G by *level*: level L_0 contains s , level L_1 contains the vertices in $N(s)$, and iteratively at step i breadth-first search defines L_i as the undiscovered vertices of $N(L_{i-1})$.

We present an implementation of BFS that uses a queue L to store the vertices to be visited.

Algorithm 1: Breadth-First Search

Data: G, s

Result: a BFS G

```

1 Mark  $s$  as Discovered;
2  $L := \text{Enqueue}(s)$ ;
3 /*  $L$  is a queue that contains the vertices discovered that have to be
   explored */;
4 while  $L \neq \emptyset$  do
5    $v := \text{Dequeue}(L)$ ;
6   foreach  $u \in N(v)$  do
7      $\text{Enqueue}(L, u)$ ;
8     if  $u$  is marked as undiscovered then
9       Mark  $u$  as discovered;
10  Mark  $v$  as explored;
```

Consider the example of Fig. 1. The BFS starts from vertex v_1 (Fig. 1(a)); vertices v_2 and v_3 , which are adjacent to v_1 , are enqueued in L (we assume v_2 is the first enqueued vertex, v_3 the second); v_1 is marked as explored, v_2 and v_3 as discovered. In Fig. 1(b) vertex v_2 (the first vertex of the queue) is explored, and vertex v_4 and v_5 are enqueued and marked as discovered (we assume v_5 is the first enqueued vertex, v_4 the second). In Fig. 1(c) vertex v_3 (the first vertex of the queue) is explored and the vertices in $N(v_3)$, are enqueued in L and marked as discovered. In Fig. 1(d)–(f) vertices v_5 , v_4 and v_6 , respectively are explored.

Fig. 1 An example of BFS. The vertices are discovered and explored starting from vertex v_1 . The discovered vertex at each step is circled, and the edges selected to discover vertices are highlighted in bold red. Notice that rectangles group the vertices at level L_1 (v_2 and v_3) and at level L_2 (v_4, v_5, v_6).

A relevant properties of BFS is that the vertices at level L_i , with $0 \leq i \leq V$, are those vertices at distance i in G from the source vertex s .

Depth-first search starts from vertex s , and explores the graph following branches, until it is possible to find unexplored vertices, thus leading to a different strategy. A recursive implementation for DFS that visit the connected component containing vertex s is given as follows:

Algorithm 2: Depth-First Search

Data: G, s

Result: a DFS G

```

1 Mark  $s$  as discovered;
2 foreach  $u \in N(v)$  do
3   if  $u$  is unexplored then
4     DFS( $G, u$ )
5  $s$  is marked as explored;
```

An iterative implementation of DFS can be given, using a stack S data structure.

Consider the example of Fig. 2. The DFS starts, as the DFS, from vertex v_1 (Fig. 2(a)); then vertices v_2 and v_3 , which are adjacent to v_1 , are considered (we assume that v_2 is considered first). In Fig. 2(b) vertex v_2 is marked as discovered and vertex v_4 and v_5 are visited (we assume that v_4 is considered first). In Fig. 2(c) vertex v_4 is marked as discovered and vertices in $N(v_4)$ are considered (we assume that v_5 is considered first). In Fig. 2(d) vertex v_5 is marked first as discovered and then as explored, since all vertex in $N(v_5)$ are already marked as discovered. In Step (e), vertex v_6 is discovered. In Step (f) vertex v_3 is discovered and Vertices v_3, v_6, v_4, v_2 and v_1 are finally marked as explored. Notice that the order in which vertices of G are discovered and explored by BFS and DFS is different. For example v_3 is the third vertex discovered by BFS and the last vertex discovered by DFS.

Breadth-first search and depth-first search have some relevant properties that we will illustrate next. First, both algorithms induce a tree (denoted as T_b for breadth-first search and as T_d for depth-first search). The vertices of T_b and T_d are those vertices of the connected component of G including the source vertex s , and the edges are those selected when marking a vertex as discovered. Consider Figs. 1 and 2; the edges of G that induce T_b and T_d , respectively, are highlighted in bold red.

Moreover, the following property for BFS holds.

Lemma 1: Let $G=(V, E)$ be a graph and let be T_b be a tree returned by the breadth-first search of G . Then, given an edge $\{u, v\}$ of G not included in T_b , it follows that u and v belong to levels L_i and L_j , with $i, j \geq 1$ such that $|i - j| \leq 1$.

Fig. 2 An example of DFS. The vertices are visited starting from vertex v_1 . The discovered vertex at each step is circled, and the edges selected to discover vertices are highlighted in red.

Moreover, the path in T_b from s to a vertex v is a shortest path from s to v in G .
The following property for DFS holds.

Lemma 2: Let $G=(V, E)$ be a graph and let be T_d be a tree returned by the depth-first search of G . Then, given an edge $\{u, v\}$ of G not included in T_d , it holds that u and v are one the ancestor of the other in T_d .

Shortest Path Algorithms

The computation of shortest paths is a fundamental problem in graph theory, with several applications in transports and in several other fields. Here we present three algorithms to compute shortest paths: Dijkstra's algorithm, Bellman-Ford algorithm and Floyd-Warshall algorithm. We assume that s is the source vertex and t is the target vertex.

Dijkstra's algorithm

Dijkstra's algorithm (Dijkstra, 1959) computes the shortest path between a source vertex s and any other vertex of the graph in a weighted graph $G=(V, E)$, where each edge in E has a non negative weight.

Dijkstra's algorithm assigns a label l to the vertices of the graph, in order to compute a shortest path from s to these vertices. The label $l(v)$ associated with a vertex $v \in V$ contains the value of a path from s to v and can be of two kinds: temporary or definitive. When a label is marked as definitive, then the algorithm has found the length of a shortest path from s to v . Temporary labels are updated at each iteration of the algorithm until all the labels of the graphs are marked as definitive.

In the first step, the label of s is initialized to 0. Any other label is marked as temporary and as value $+\infty$. The algorithm iterative step considers the vertex v having a label with minimum value, and it marks the label of v as definitive. For each vertex $u \in N(v)$ with a temporary label, it is computed the value $l(v) + w(\{v, u\})$; if $l(u) \geq l(v) + w(\{v, u\})$, then $l(u)$ is updated to $l(v) + w(\{v, u\})$, else $l(u)$ is not modified.

Algorithm 3: Dijkstra's Shortest Path

Data: G, s

Result: shortest paths between s and any other vertex of G

```

1 foreach  $u \in V$  do
2    $l(u) := +\infty$ ;
3  $l(s) := 0$ ;
4  $l(s)$  is marked as definitive;
5  $S = \{s\}$ ;
6 /*  $S$  contains the vertices whose label is marked as definitive */;
7 foreach  $v \in N(s)$  do
8    $l(v) := w(\{s, v\})$ ;
9 while  $(V \setminus S) \neq \emptyset$  do
10  Consider  $v \in (V \setminus S)$  with minimum  $l(v)$ ;
11  foreach  $u \in N(v)$  do
12     $l(u) := \min(l(u), l(v) + w(\{u, v\}))$ ;
13     $l(v)$  is marked as definitive;
14     $S := S \cup \{v\}$ ;
```

Bellman-Ford algorithm

The Bellman Ford algorithm (Bellman, 1958; Floyd and Rivest, 1975) computes a shortest path from s to any other vertex of the graph $G=(V, E)$, also in the case that the weighted graph contains negative edge weights. The presence of negative cycles (cycles whose edge weights sum to a negative value) is also detected by Bellman-Ford algorithm. In this case, by traversing such a cycle, we decrease the total weight of the path arbitrarily, hence the algorithm returns the indication that no solution exists, otherwise it returns the values of a shortest path between s and a vertex v .

Bellman-Ford algorithm applies a strategy similar to that of Dijkstra's algorithm, that is it introduces a label $l(v)$ that is assigned to each vertex in $v \in V$. The label $l(v)$ is iteratively updated until it is equal to the length of a shortest path from s to v . While

Dijkstra's algorithm updates the labels using the outgoing edges of the last vertex whose label has been marked as definitive, Bellman-Ford algorithm iterates $|V| - 1$ updates, using for the update each edge in E .

Algorithm 4: Bellman-Ford Shortest Path

Data: G, s

Result: shortest paths between s and any other vertex of G ; if there exists a negative cycle, it outputs its existence

```

1 for  $u \in V$  do
2    $l(u) := +\infty$ ;
3  $l(s) := 0$ ;
4 for  $i = 1$  to  $|V| - 1$  do
5   foreach edge  $\{u, v\} \in E$  do
6      $l(v) := \min(l(u), l(v) + w(\{u, v\}))$ ;
7 foreach edge  $\{u, v\} \in E$  do
8   if  $l(u) > l(v) + w(\{u, v\})$  then
9     Return("Negative cycle");
```

Floyd-Warshall algorithm

Floyd-Warshall algorithm (Floyd, 1962; Warshall, 1962) is a dynamic programming algorithm to compute the shortest path between all pairs of vertices in a graph. The graph can be weighted and can have negative edge weights, but not negative cycles. First, we describe the dynamic programming recurrence of the Floyd-Warshall algorithm. Given a weighted graph $G = (V, E)$, let the vertices in V be $\{v_1, v_2, \dots, v_n\}$. Define a function $P[i, j, k]$ that returns the weight of a shortest path from v_i to v_j , that contains only the vertices $v_1, v_2, \dots, v_k$ as intermediate vertices. Floyd-Warshall algorithm exploits a dynamic programming strategy to compute function $P[i, j, k]$. $P[i, j, k]$ can be computed considering two possible cases: (1) vertex v_k belongs to a shortest path between v_i and v_j or (2) v_k does not belong to a shortest path between v_i and v_j . The dynamic programming recurrence to compute $P[i, j, k]$ is then:

$$P[i, j, k] = \min \begin{cases} P[i, j, k-1] \\ P[i, k, k-1] + P[k, j, k-1] \end{cases}$$

In the base case, that is when $k=0$, it holds $P[i, j, 0] = w(\{v_i, v_j\})$. We present here an iterative algorithms that implements the recurrence given above.

Algorithm 5: Floyd-Warshall Algorithm

Data: G

Result: Shortest paths between all pairs of vertices

```

1 for  $i = 1$  to  $|V|$  do
2   for  $j = 1$  to  $|V|$  do
3      $P[i, j, 0] := w(\{v_i, v_j\})$ ;
4     /* We assume that  $w(\{v_i, v_j\}) = +\infty$  if  $\{v_i, v_j\} \notin E$  */
5 for  $k = 1$  to  $|V|$  do
6   for  $i = 1$  to  $|V|$  do
7     for  $j = 1$  to  $|V|$  do
8        $P[i, j, k] := \min(P[i, j, k-1], P[i, k, k-1] + P[k, j, k-1])$ ;
```

The recurrence computes only the weight (or the length for unweighted graphs) of a shortest path between v_i and v_j . However, a shortest path can be computed for example by using a matrix $PA[i, j, k]$, where the entries are used to memorize the intermediate

vertices. The entries in matrix $PA[i, j, k]$ represent the predecessor of vertex v_j on a shortest path from v_i to v_j that contains only vertices in $v_1, v_2, \dots, v_k$. We present the recurrence to compute $PA[i, j, k]$, for $k \geq 1$:

$$PA[i, j, k] = \begin{cases} PA[i, j, k-1] & \text{if } P[i, j, k-1] \geq P[i, k, k-1] + P[k, j, k-1] \\ PA[k, j, k-1] & \text{if } P[i, j, k-1] > P[i, k, k-1] + P[k, j, k-1] \end{cases}$$

When $k=0$, $PA[i, j, 0] = v_i$. Notice that Floyd-Warshall algorithm computes a solution to the all-pairs shortest path problem, that is it computes a shortest path between any pair of vertices of the graph, while Dijkstra's algorithm and Bellman-Ford algorithm computes the shortest path from a given source vertex s .

Ford-Fulkerson Algorithm

The Ford-Fulkerson algorithm (Ford and Fulkerson, 1962) allows to compute the maximum flow in a graph. Consider a graph G , with two specific vertices s and t , called the source and the sink, respectively. Each edge of the graph is associated with a *capacity*, which denotes the maximum flow that is allowed on that edge.

Given a graph $G=(V, E, c)$ where c is a function that associates a capacity $c(\{u, v\}) \geq 0$ with each edge $\{u, v\} \in E$, a source $s \in V$ and a sink $t \in V$, the maximum flow problem asks for the maximum flow F that can be sent in G from s to t without violating the edge capacities.

Formally, let $F : E \rightarrow \mathbb{R}$ be a flow function. The flow F from s to t must satisfy the following constraints:

- $F(\{u, v\}) \leq c(\{u, v\})$ (capacity constraints)
- $F(\{u, v\}) = -F(\{v, u\})$ (skew symmetry)
- $\sum_{u \in V} F(\{v, u\}) = 0$, $\forall v \in V \setminus \{s, t\}$ (flow conservation).

Consider a flow F in G , we define the *residual graph* $G_F=(V, E, c_F)$, where the capacity c_F of each edge in E is defined as follows:

$$c_F(\{u, v\}) = c(\{u, v\}) - F(\{u, v\})$$

The Ford-Fulkerson algorithm computes the maximum flow in a graph. Given a flow F , the Ford-Fulkerson algorithm looks for an augmenting path in G_F , that is a path π from s to t in G_F such that the edges in the path have a positive capacity, thus allowing some flow to be sent from s to t . The algorithm is iterated until it is possible to find an augmenting path.

Algorithm 6: Ford-Fulkerson Algorithm

Data: $G=(V, E, c)$, $s, t \in V$

Result: A maximum flow from s to t in G

```

1 foreach  $\{u, v\} \in E$  do
2    $F(\{u, v\}) := 0$ ;
3    $F(\{v, u\}) := 0$ ;
4 while There exists an augmenting path  $\pi$  in  $G_F$  do
5   define  $c_F(\pi) = \min(c_F(\{u, v\}) : \{u, v\} \text{ belongs to } \pi)$ ;
6   foreach  $\{u, v\}$  in  $\pi$  do
7      $F(\{u, v\}) := F(\{u, v\}) + c_F(\pi)$ ;
8      $F(\{v, u\}) := -F(\{u, v\})$ ;
```

A cut in a graph G is a set of edges whose removal disconnect G . A *minimum cut* is a cut whose edges has minimum weight. A well-known result in graph theory is that the maximum flow of a graph is equal to the value of a minimum cut in a graph. Thus, Ford-Fulkerson algorithm can be used to compute a minimum cut of a graph.

Minimum Spanning Tree

In this section we present two algorithms to compute a minimum spanning tree: Kruskal's algorithm and Prim's algorithm. Both algorithms compute a minimum spanning tree of a weighted graph $G=(V, E)$ with a greedy strategy, but differ in the way vertices are added to the spanning tree.

Kruskal's algorithm

Kruskal's algorithm (Kruskal, 1956) starts from a forest consisting of an empty set of edges, and constructs a forest by greedily adding edges of minimum weight. Let $G=(V, E)$ be a graph and let $F=(V_F, E_F)$ be a forest, with $V_F=V$ and $E_F \subseteq E$. F is initialized as follows: $V_F=V$ and $E_F=\emptyset$. Kruskal's algorithm selects the edge $\{u, v\} \in E/E_F$ of minimum weight such that u and v belong to different trees of forest F ; $\{u, v\}$ is added to E_F and the trees containing u and v are merged.

Fig. 3 shows how the edges of a graph G are added to E_F . Notice that at each step, the selected edge is that of minimum weight that does not induce a cycle, independently from the fact that the selected edge shares an endpoint with other edges in E_F or not. Notice that in Fig. 3(a) F consists of six trees, each one containing of a single vertex. In Fig. 3(b), Kruskal's algorithm select edge $\{v_1, v_2\}$ of minimum weight and merges the trees containing v_1 and v_2 . Hence, F consists of five trees: the tree T_1 having vertices v_1, v_2 and edge $\{v_1, v_2\}$, and four trees each one containing a single vertex of v_3, v_4, v_5, v_6 . In Fig. 3(c), Kruskal's algorithm selects edge $\{v_3, v_6\}$ and merges the trees containing v_3 and v_6 . Hence, F consists of four trees: the tree T_1 , the tree T_2 having vertices v_3, v_6 and edge $\{v_3, v_6\}$, and two trees each one containing a single vertex of v_4, v_5 . In Fig. 3(d), Kruskal's algorithm selects edge $\{v_2, v_5\}$ and merges the tree T_1 and the tree containing v_5 . Hence, F consists of four trees: the tree T'_1 containing vertices v_1, v_2 and v_5 and edges $\{v_1, v_2\}$ and $\{v_2, v_5\}$, tree T_2 and one tree containing vertex v_4 . In Fig. 3(e), edge $\{v_2, v_3\}$ is selected and trees T'_1 and T_2 are merged, while in Fig. 3(f) $\{v_4, v_5\}$ is selected and a minimum spanning tree of G is finally computed.

Prim's algorithm

Prim's algorithm (Prim, 1957) starts from an empty tree, and constructs a subtree of the input graph by greedily adding edges of minimum weight. However, while Kruskal's algorithm constructs a forest, Prim's algorithm adds edges that induce a connected subtree at each step of the algorithm. Formally, let $G=(V, E)$ be a graph and let $T=(V_T, E_T)$ be a tree, with $V_T \subseteq V$ and $E_T \subseteq E$. T is initialized as follows: $V_T=\{r\}$, for some vertex $r \in V$ and $E_T=\emptyset$. Prim's algorithm selects the edge $\{u, v\} \in E/E_T$ of minimum weight such that exactly one of u, v , without loss of generality v , belongs to V_T ; then $\{u, v\}$ is added to E_T and u is added to V_T . Notice that, since for each selected edge $\{u, v\}$, $v \in V_T$ and $u \in V/V_T$, it follows that $\{u, v\}$ does not induce a cycle in G with edges of E_T .

Fig. 4 shows how the edges of a graph G are added to E_T by Prim's algorithm. At each step, the selected edge is that of minimum weight that contains a vertex in V_T and a vertex in V/V_T . Assume that vertex r is v_1 , that is $V_T=\{v_1\}$ in the first step. Then Prim's algorithm in Fig. 4(b) adds edge $\{v_1, v_2\}$ to E_T and adds vertex v_2 to V_T . In Fig. 4(c), Prim's algorithm adds edges $\{v_1, v_3\}$ to E_T and v_3 to V_T . Notice that $\{v_1, v_3\}$ is not the edge having minimum weight in E/E_T of Fig. 4(b), since the edge of minimum weight in E/E_T of Fig. 4(b) is $\{v_3, v_6\}$, but $v_3, v_6 \notin V_T$. In Fig. 4(d)–(f), Prim's algorithm selects edges $\{v_3, v_6\}$, $\{v_2, v_5\}$ and $\{v_5, v_4\}$, respectively, adds these edges to E_T and adds vertices v_6, v_5 , and v_4 , respectively, to V_T . In Fig. 4(f) a minimum spanning tree of G computed by Prim's algorithm is shown.

Nearest Neighbour Algorithm

One of the most studied problem in graph theory in the last fifty years is the *Traveling Salesman Problem* (TSP). Given a weighted graph $G=(V, E)$, and a vertex $s \in V$, TSP asks for a circuit of minimum weight that starts and ends in vertex s and that contains all the vertices of G .

Since the TSP is NP-hard, heuristics and approximation algorithms have been considered to solve the problem. These algorithms have polynomial-time complexity, but may returns suboptimal solutions. The nearest neighbour algorithm is a well-known heuristic for TSP. At each step, it considers a current vertex v and it considers the edges having minimum weight that connects v to an unvisited vertex u ; u is then considered as the current vertex. Notice that the heuristics may not be able to find a feasible solution

Fig. 3 An example of execution of Kruskal's algorithm. The bold red edges added to those added to E_F .

Fig. 4 An example of execution of Prim's algorithm. The bold red edges added to those added to E_T .

of TSP (that is a circuit that contains all the vertices of G), even if one exists. Moreover, even if it finds a feasible solution of TSP, the solution returned can be α times more than the optimal one, for each constant $\alpha > 0$, and may return the worst possible feasible solution (Gutin *et al.*, 2002).

Analysis and Assessment

In this section we discuss the time-complexity of the algorithms presented in Section Methodologies.

Breadth-First Search and Depth-First Search

Breadth-first search and depth-first search can be implemented so that their time-complexity is $O(|V| + |E|)$ (Cormen *et al.*, 2009). More specifically, implementation of breadth-first search uses a queue to store and retrieve the vertices to be visited, while depth-first search uses a stack to store and retrieve the vertices to be visited.

Shortest Path Algorithms

Dijkstra's algorithm using a Fibonacci heap in the implementation can achieve a time-complexity of $O(|V| \log |V|)$ (Cormen *et al.*, 2009). The Bellman-Ford algorithm has a time-complexity of $O(|V||E|)$ (Cormen *et al.*, 2009). Floyd-Warshall algorithm has a time-complexity of $O(|V|^3)$, due to the iteration of line- 5–8 of Algorithm 5 (Cormen *et al.*, 2009).

Ford-Fulkerson Algorithm

The time-complexity of the Ford-Fulkerson algorithm described in Section Methodologies depends on the algorithm used to find an augmenting path in the residual graph G_F . Notice that for some choice of the algorithm to compute the augmenting path, the Ford-Fulkerson may not even terminate. An augmenting path in the residual graph G_F can be computed efficiently using a BFS search. In this case the time-complexity of the algorithm is $O(|V||E|^2)$ (Cormen *et al.*, 2009).

Minimum Spanning Tree Algorithms

Kruskal's algorithm can implemented so that its running time is $O(|E| \log |E|)$, by using a disjoint-set data structure to store disjoint trees of forest, and applying Union-Find operations to merge two trees and find the tree containing a given vertex, respectively. In particular, the disjoint-set data structure can be implemented efficiently with the union-by-rank and path-compression heuristics.

Prim's algorithm can achieve a time-complexity $O(|E| \log |V|)$, using a binary heap in the implementation (Cormen *et al.*, 2009).

Traveling Salesman Person

The TSP problem is an NP-hard problem, and it is one of the of the classic NP-hard problems considered in Garey and Johnson (1995). The NP-hardness of TSP, even in the restricted case that each edge has weight equal to one, that is the graph in unweighted, follows from the NP-completeness of the problem of finding a Hamiltonian cycle in a graph (Karp, 1972). Indeed, in an

unweighted graph an optimal solution of TSP is a Hamiltonian cycle, thus from the NP-completeness of computing a Hamiltonian cycle follows the NP-hardness of TSP.

The time-complexity of nearest neighbour algorithm for TSP is $O(|V|)$, since it performs at most $|V|$ iteration and in each iteration it visits at most $|E|$ edges.

Illustrative Examples

In this section we present some examples where graph algorithms have been applied in computational biology.

Graph Traversal Algorithms

Depth-first search and breadth first search have many application in graph theory and in computational biology. Two notable examples are the computation of the connected components of a graph and strongly connected components of a directed graph, and the test of bipartiteness of a graph.

Depth-first search can be applied to compute the partition of a directed graph in strongly connected components. The decomposition of a directed graph in strongly connected components has been applied as a relevant step for the synthesis of signal transduction networks. The approach applied in [Albert et al. \(2007, 2008\)](#) aims to remove false positive of a signal transduction network by constructing a sparsest graph that maintains all reachability relationships of a given directed graph. This goal is reached by first decomposing the directed graph in strongly connected components, and then solving a second problem (called binary transitive reduction) on each strongly connected component independently.

Breadth-first search can be applied to test if a graph $G=(V,E)$ is bipartite, that is if the vertices of G can be partitioned in two disjoint sets V_1 and V_2 such that there is no edge between two vertices of V_1 (of V_2 , respectively). Testing bipartiteness is a fundamental in many practical problems, a notable example in computational biology is haplotyping (for a survey see [Bonizzoni et al., 2003](#)). One relevant problem in haplotyping is the single individual haplotype problem ([Lippert et al., 2002](#)). The single individual haplotype problem asks for a bipartition of a set of fragments coming from a haplotype, in order to be able to reconstruct the two copies of a haplotype from fragments. Fragments are usual represented as vertices of a graph, called conflict graph, and there exists an edge between two vertices if the corresponding fragments have different values in some positions. The reconstruction of the two copies of a haplotype corresponds to a bipartition of the conflict graph. Several variants of the problem have been proposed to correct errors in fragments ([Lippert et al., 2002](#)).

Ford-Fulkerson Algorithm

The computation of maximum flow and minimum cut has many applications in computational biology. The computation of a minimum cut has been applied for example to design heuristics for the supertree problem. Given a set S of trees, the goal of the supertree problem is to compute a supertree by combining different trees in S . Two natural heuristics for this problem apply iteratively a minimum cut on a graph that represents the relations among leaves ([Semple and Steel, 2000](#); [Page, 2002](#)). A similar strategy has been applied also in [Dondi et al. \(2017\)](#) to design an approximation algorithm for the problem of correcting a set of orthologous/paralogous relations between genes.

Spanning Trees

Spanning trees have been widely applied in the context of networking, but has found application also in computational biology. An approach for the clustering of microarray gene-expression data is based on the computation of a minimum spanning tree of a graph G that represents multi-dimensional gene expression data ([Xu et al., 2001](#)). An interesting property of this graph is that cluster corresponds to minimum spanning tree, thus a cluster of the expression data is computed by computing a partition of G in minimum spanning trees.

Traveling Salesman Person

The TSP problem has been applied to many problems in several contexts. One notable example in computational biology is the shortest superstring problem, a problem that has application in the context of genome assembly.

Given a set of strings that have to be assembled, a graph representation define a vertex for each string and an edge for each pair of overlapping strings and the weight of an edge is the length of the overlapping. Then a shortest superstring of the given strings corresponds to a solution of a variant of TSP in the associated graph ([Mucha, 2013](#)).

Closing Remarks

We have reviewed some of the main graph algorithms. First we have presented algorithms related to graph traversal (depth-first search and breadth-first search) and we have reviewed algorithms for the computation of shortest paths. We have considered the

Ford-Fulkerson algorithm for the computation of the maximum flow. Then we have reviewed the Kruskal's algorithm and the Prim's algorithm for the computation of the minimum spanning tree. Finally, we have presented the traveling salesman problem and a heuristic for its solution, the nearest neighbour algorithm. Moreover, we have presented some applications of these algorithms to problems in computational biology.

Network Centralities and Node Ranking

Raffaele Giancarlo, Daniele Greco, Francesco Landolina, and Simona E Rombo, University of Palermo, Palermo, Italy

Introduction

Studying the significant role that single nodes play in a graph representing a network may provide important insights into the network structure and the functions that it implicitly codifies. Ranking or identifying the node importance is one of the first steps to understand the hierarchical organization of biological networks (Liu *et al.*, 2012). To this aim, the number of edges outcoming from a node, that is, its “degree,” is the simplest and intuitive indicator of how much important is that node. Traditionally, large degree nodes (also called *hubs*) are deemed as important nodes in a network. To cite another example of characterization of the importance of a node in a network, one can refer to its *H-index*, defined as the maximum integer h such that the considered node has at least h neighbours whose degrees are greater than h . Higher H-index indicates that the node has a number of neighbours with high degree. Compared with degree, H-index can better capture the spreading importance. A node with higher degree infects many neighbours at start times, while the spread process will cease quickly if its neighbours have low degrees.

In general, more sophisticated centrality indices have been proposed in the literature in order to provide a quantification of the importance, in terms of centrality, of nodes in a network. A plethora of different characterizations are available in literature, each of them scoring a different structural property for the network elements (Brandes and Erlebach, 2005).

Historically, centrality indices were introduced in the context of social network analysis to discover the most influential individuals in a community (Bonacich, 1972; Freeman, 1978; Leo, 1953). In biological sciences, they are employed to identify key players in biological processes modeled as biological networks such as gene regulatory, metabolic and protein-protein interaction networks (Koschützki and Schreiber, 2008; Pavlopoulos *et al.*, 2011). Furthermore, since *structure always affects function*, (Strogatz, 2001) centrality analysis aims at assessing the extent to which topological prominence predicts biological importance.

For example, Joeng *et al.* showed that high-degree nodes (hubs) in yeast protein interaction network are enriched in essential proteins, suggesting that essentiality is related to the central role that hubs play in mediating interactions among a large number of other, less connected, proteins (Jeong *et al.*, 2001). As a complementary approach, Gerstein *et al.* found that in regulatory networks, essentiality better correlates with betweenness-centrality -the number of shortest paths passing through a node- than degree-centrality (Yu *et al.*, 2007). Finally, Przytycka *et al.* provided a careful analysis of six different *S. cerevisiae* protein networks with different centrality measures, showing that non-essential protein-hubs are no more important than essential protein-hubs in maintaining the interactome connectivity, and that those centrality indices which better predicts nodes involved in topological network cohesiveness, are no better predictors for essential genes than degree-centrality (Zotenko *et al.*, 2008).

These examples clearly illustrate how the same input network can be valuable analyzed using different centrality measures, yielding complementary, contrasting, still informative biological perspectives on its constituents.

Ranking algorithms based on node centrality measures have been proposed and applied in the bioinformatics domain (Pavlopoulos *et al.*, 2011).

This manuscript aims at providing an overview of the main node centrality measures (Section Centrality Measures), by also showing some 5 we draw our conclusions. The next section is devoted to introduce some basic definitions needed for the full understanding of the manuscript.

Basics

We represent networks by *undirected, unweighted* graphs $G=(V,E)$, where V denotes the set of nodes and E the set of edges connecting them. G may also be represented in terms of its *adjacency matrix* $A=[a_{ij}]$, where $a_{ij}=1$ if $\{i,j\} \in E$ and 0 otherwise.

A *walk* from node u to node v is an alternating list $v_0, e_1, v_1, e_2, v_2, \dots, e_k, v_k$ of vertices and edges such that for $1 \leq i \leq k$ the edge e_i has endpoints v_{i-1} and v_i , with $v_0=u$ and $v_k=v$. A *trail* is a walk in which no edge is traversed more than once. A *path* is a trail in which no node is visited more than once.

The *length* of a walk is the number of edges traversed. We define the *distance* d_{uv} as the length of a *shortest* path connecting vertices u and v . Where necessary, directed graphs are introduced as well.

Centrality analysis is a type of network structural analysis (Ma and Gao, 2012). A centrality index induces a ranking of vertices (or edges) of a graph G by assigning them a real value based uniquely on its network structure.

Accordingly, a minimal requirement for a real-valued function $c: V \rightarrow \mathbb{R}$ to be a centrality index is that it can be computed having only access to a representation of G , e.g., its adjacency matrix.

Two graphs $G=(V_G, E_G)$ and $H=(V_H, E_H)$ are isomorphic ($G \simeq H$) if there exists a bijection $\phi: V_G \rightarrow V_H$ such that $(u,v) \in E_G$ if and only if $(\phi(u), \phi(v)) \in E_H$.

We recall from (Brandes and Erlebach, 2005) the definition of *structural index*.

Definition 1: (Structural Index) Let $G=(V,E)$ be a weighted, directed or undirected graph and let X represent the set of vertices or edges of G , respectively. A real-valued function s is called a structural index if and only if the following condition is satisfied: $\forall x \in X: G \simeq H \Rightarrow s_G(x) = s_H(\phi(x))$, where $s_G(x)$ denotes the value of $s(x)$ in G .

Every centrality index c discussed here is a structural index. In particular, we are only concerned in the induced ranking of vertices (or edges). Therefore, we consider that a vertex u is *more important* than another vertex v , with respect to c , if $c(u) > c(v)$.

It is worth noting that the above definition holds a fundamental limitation: real values assigned to vertices by a centrality index *do not* account for their *relative* importance. As pointed out in, (Brandes and Erlebach, 2005) the difference or ratio of two centrality values cannot be interpreted as how much more central one element is than the other. Indeed, other metrics and methods have to be used for this purpose (Lawyer, 2015).

Centrality indices serve only the purpose of producing a ranking which allows the identification of the most prominent nodes or edges in the network with respect to a given structural property.

Centrality Measures

Degree and Walk-Based Centralities

In this section, we present centrality measures based on the set of walks of G originating (or terminating) at a particular vertex, spanning from walks of length 1 (degree centrality) to length infinity (eigenvector centrality).

Degree centrality

Degree centrality $c_D(i)$ is the simplest measure of centrality, which assigns to each vertex i in G its degree:

$$c_D(i) = \sum_{j=1}^N A_{ij} \quad (1)$$

In case of a directed network, two separate centralities are defined: the *in-degree* $c_D^-(i)$ and *out-degree* $c_D^+(i)$ centralities, that is, the number of in-going and out-going edges of i , respectively.

Degree centrality is a local centrality index, ranking vertices of G according to their immediate neighborhood: the larger the number of interactions, the more important the node in the network. Furthermore, we can interpret every edge as a walk of length 1, and consider $c_D(i)$ as counting the number of paths of length 1 originating (or terminating) at node i .

High degree-centrality nodes are called *hubs*. In scale-free networks, the removal of hubs rapidly fragments the network, leading to different isolated connected components (Barabási and Pósfai, 2016). Under the assumption that an organism's function depends on the connectivity among various parts of its interactome, Jeong *et al.* (2001) correlate the degree of proteins in a *S. cerevisiae* protein interaction network to the lethality of their removal.

Furthermore, in graph evolution models high vertex degrees accounts not only for cohesiveness, but also for age. Indeed, in metabolic networks (Fell and Wagner, 2000) show that the metabolites with the highest connectivity are part of the oldest "core" metabolism of *E. coli*.

Katz centrality

In contrast with degree centrality, Katz status index (Leo, 1953) takes into account *all* walks originating (or terminating) at a given node i , and weights them according to their length. Intuitively, the greater the length the less influential a connection is.

Mathematically, Katz centrality $c_K(i)$ of vertex i is defined as:

$$c_K(i) = \sum_{k=1}^{\infty} \sum_{j=1}^N \alpha^k (A^k)_{ji} \quad (2)$$

The k -th power of the adjacency matrix A holds the total number of walks of length k between any two vertices. In order for the infinite sum to converge, the attenuation factor α has to be chosen in $[0, \frac{1}{\lambda_1}]$ where λ_1 is the largest eigenvalue of A (Ferrar, 1951). In this case, the following matrix form can be used to compute the centrality values:

$$\vec{c_K} = \left((I - \alpha A^T)^{-1} - I \right) \vec{1_N} \quad (3)$$

where $\vec{1_N}$ is the identity vector of size N (the number of nodes) with all entries set to 1, I is the $N \times N$ identity matrix, A^T denotes matrix transposition of A and $()^{-1}$ denotes matrix inversion.

Recently, Fletcher and Wennekers (2017) studying firing activity in neural networks, have shown Katz centrality to be the best predictor of firing rate with almost perfect correlation for all types of neural networks considered.

Eigenvector centrality

Bonacich's Eigenvector centrality (Bonacich, 1972) acknowledges the fact that not all the connections are equal. Recursively, the importance of a vertex depends both on the number and the importance of its neighbours, with high-scoring neighbours contributing more than low-scoring ones.

In the following, we will consider a graph G which is undirected, connected and unweighted. The eigenvector centrality x_i of node i , is proportional to the sum of the eigenvector centralities of its immediate neighbours:

$$x_i = \frac{1}{\lambda} \sum_{j \in G} A_{ij} x_j \quad (4)$$

where λ is a positive constant. In vector form, it can be rewritten as the eigenvector equation:

$$A \mathbf{x} = \lambda \mathbf{x} \quad (5)$$

In general, there are multiple eigenvalues λ for which a non-zero eigenvector satisfying Eq. (5) exists. Since G is undirected and connected, its adjacency matrix A results in a nonnegative, irreducible real matrix. Under these conditions, by the Perron-Frobenius theorem, (Gantmacher, 1960) there exists a unique largest eigenvalue $\lambda_1 = \lambda_{\max}$ which is real and positive. The corresponding eigenvector $\mathbf{x}^*$ is unique up to a common factor and contains entries which are both nonzero and of the same sign. Therefore, we take its absolute value and normalize it:

$$\mathbf{x}_{EG} = \frac{|\mathbf{x}^*|}{\|\mathbf{x}^*\|} \quad (6)$$

The eigenvector centrality $c_{EG}(i)$ of node i is defined as the i -th component of $\mathbf{x}_{EG}$.

As discussed in, (Borgatti and Everett, 2006) eigenvector centrality can be regarded as an elegant summary of Leo (1953), Hoede (1978) and Hubbell's measures (Hubbell, 1965). Notably, Google's Page Rank (Page et al., 1999) is a variant of eigenvector centrality.

Zotenko et al. (2008) used eigenvector centrality in comparison with other centrality indices, to identify network hubs in *S. cerevisiae* protein-protein interaction networks. Other applications include prediction of synthetic genetic interactions (Paladugu et al., 2008) and identification of putative gene-disease associations on a literature mined gene-interaction network (Özgür et al., 2008).

Subgraph centrality

The Subgraph centrality (Estrada and Rodriguez-Velazquez, 2005) of the vertex i is equal to the weighted sum of all closed walks that start and terminate at vertex i . As this is an infinite sum, convergence is guaranteed assigning walks of length k the weight $\frac{1}{k!}$. Thus, the subgraph centrality $c_{SG}(i)$ of node i is defined as:

$$c_{SG}(i) = \sum_{k=0}^{\infty} \frac{(A^k)_{ii}}{k!} \quad (7)$$

Closed walks are directly related to the subgraphs of the network (e.g., triangles). Furthermore, smaller subgraphs are given more weight than larger ones, based on the observation that real-world networks are motif-rich (Alon, 2007).

In biological networks, subgraph centrality has been used mostly for the identification of essential proteins in yeast protein networks (Estrada, 2006, 2010; Zotenko et al., 2008). According to Estrada (2006) subgraph centrality slightly outperform degree centrality in identifying essential proteins in yeast protein network and shows similar performance with eigenvector centrality.

Shortest-Paths Based Centralities

In this section, we present centralities based on the set of all shortest paths and distances within graphs. Unless otherwise stated, we will assume the input graph $G=(V,E)$ to be connected.

Eccentricity centrality

Let $ecc(u)$ be the maximum distance between u and any other vertex v in the network. The quantity $ecc(u)$ is the *eccentricity* of u . Eccentricity centrality (Hage and Harary, 1995) $c_E(u)$ is defined as the inverse of $ecc(u)$:

$$c_E(u) = \frac{1}{ecc(u)} = \frac{1}{\max\{d_{uv} : v \in V\}} \quad (8)$$

The greater $c_E(u)$ the more proximal the node u to any other node v in the network. In graph theory, (Harary, 1969) the set of nodes of G with minimum eccentricity $ecc(u)$, and thus maximum $c_E(u)$, is denoted as $C(G)$, the *center* of G .

In biological networks, the computation of high-eccentricity nodes in the metabolic network of *E. coli* allowed to predict some of the most central substrates involved in energetics, signalling, and also specific (Glycolysis, Citrate cycle) pathways of the cell (Wuchty and Stadler, 2003).

Closeness centrality

In contrast with eccentricity which considers only the longest shortest paths, closeness centrality $c_C(u)$ uses all the shortest paths between u and any other vertex v in the network.

Closeness-centrality $c_C(u)$ is defined as the reciprocal of *farness*, (Bavelas, 2017) the sum of distances between u and all other vertices:

$$c_C(u) = \frac{1}{\sum_{v \in V} d_{uv}} \quad (9)$$

Closeness centrality can be thought as the average distance between the node u and all other nodes in the graph. Therefore, the shorter the distance between u and any other vertex v , the more central the node is.

Closely related to $c_C(u)$, the *radiality* index $c_R(u)$ adapted from Valente and Foreman (1998) for undirected graphs, measures how well a node is integrated in the network. Let $diam(G)$ be the *diameter* of G , the maximum distance between any two vertices in the graph G .

The radiality $c_R(u)$ if node u is defined as:

$$c_R(u) = \frac{\sum_{v \in V} (diam(G) + 1 - d_{uv})}{N - 1} \quad (10)$$

where N denotes the number of vertices. The major difference with closeness centrality is that $c_R(u)$ reverses distances with respect to the diameter instead of taking the reciprocal.

Ma and Zeng (2003) used closeness centrality to identify the top central metabolites in *E. coli* metabolic network. In Mazurie et al. (2010) a normalized version of closeness centrality (Sabidussi, 1966) is used as a network structure descriptor in a cross-species comparison of metabolic networks.

Both closeness and radiality can also be applied to directed strongly connected networks.

Betweenness centrality

The betweenness of a vertex v as introduced in the context of social networks by Freeman (1978) refers to the extent to which a vertex v can control, or monitor, communication between any two other vertices in the network.

Under the assumption that information is transmitted along shortest paths, betweenness centrality measures how often v occurs on all shortest paths between any other two nodes in the network.

For a given pair of vertices s, t let σ_{st} be the number of all shortest-paths between s and t , and $\sigma_{st}(v)$ the number of shortest-paths between s and t containing v . We denote with $\delta_{st}(v)$:

$$\delta_{st}(v) = \frac{\sigma_{st}(v)}{\sigma_{st}} \quad (11)$$

the *fraction* of all shortest-paths between s and t containing v . The quantity $\delta_{st}(v)$ can be interpreted as the probability that a "message" from s to t goes through v . Iterating over all possible vertex pairs, the shortest-path betweenness centrality $c_{SPB}(v)$ of vertex v is defined as:

$$c_{SPB}(v) = \sum_{s \neq v \in V} \sum_{t \neq v \in V} \delta_{st}(v) \quad (12)$$

Thus, the larger the overlap between the set all of shortest paths and the set of shortest paths containing v , the more central the node v .

Both Yu et al. (2007) and Joy et al. (2005) highlight proteins with high betweenness but low degree to be prominent in yeast PPI networks, suggesting they could support modular organization acting as key connector nodes between different, more densely connected, functional modules.

In mammalian transcriptional regulatory networks, Potapov et al. (2005) report high degree and high betweenness genes to be enriched with genes having tumor-suppressor or proto-oncogene properties.

Examples

In this section we propose examples in order to show how some of the centrality measures described in the previous sections can be calculated.

Let $G=(V,E)$ the graph shown in Fig. 1 together with its adjacent matrix. We focus on three measures, Degree, Betweenness and Closeness Centrality, respectively, that have been applied to G in order to highlight which nodes have a high value of the considered measure and what happens to the graph if one of these nodes is eliminated.

Before going on with we recall the notion of *all pair shortest path*, that concerns the search of all the shortest paths for each pair of nodes in an input graph. To do it, there are several techniques such as Floyd-Warshall (efficient for dense graphs) and Johnson (efficient for spread graphs) suitably adapted for the case of unweighted and undirected graphs (Aho et al., 1974).

Table 1 shows *all pair shortest paths* computed for the graph G in Fig. 2. It should be pointed out that the identified paths shown in the table have only been inserted once, since they can be run in both directions (undirected) as part of the symmetric array represented by the adjacency matrix of G .

Degree Centrality

We first consider the Degree Centrality, according to which a particular node is central to the network if it is one of the most active within it, i.e., if the node participates to a bigger number of associations/edges than the others nodes. An active node is a node that interacts frequently with the others by indicating which nodes are in direct contact with each other. Nodes with a high degree centrality could be interpreted as *crucial nodes* for the network considered, and even though it is easy to calculate, it provides an

Fig. 1 An input graph $G=(V, E)$ and its adjacent matrix.

important information to identify the essential nodes in the graph. The index of a node can be defined as the number of nodes adjacent to it, or as the *cardinality of its neighborhood*. Consider the adjacent matrix of G shown in [Fig. 1](#). The degree centrality of a node can be computed by adding all non-zero values to the columns (or rows):

$$c_D(i) = \sum_{j=1}^N A_{ji} = \sum_{j=1}^N A_{ij} \quad (13)$$

Example: By calculating the index of node 3, we have to sum all the numbers of its row (column), obtaining an index of 6. [Table 2](#) shows the values of degree centrality for each node in G .

[Fig. 1](#) illustrates what happens if the node scoring the highest value of Degree Centrality is removed from the network. In particular, in that case G becomes a disconnected graph, including two singletons and two small sub-graphs of three and four nodes, respectively. This means that, more in general, by eliminating from the network those nodes scoring high values of Degree Centrality many knots could not be reached.

Closeness Centrality

Closeness Centrality is also based on the principle of the shortest path, as already specified in Section Centrality Measures. The intuition behind the closeness centrality measures is the following: increasing the length of the shortest path between a node and all the others, the centrality of the considered node should decrease since a node is less central when it is farther from the other knots. It is immediately noted that this type of centrality depends not only on direct arcs, but also on indirect ones, especially when two nodes are not adjacent to each other. The calculation of Closeness Centrality, previously quoted in [Formula \(9\)](#), is simply the inverse of the sum of the distances of all the shortest paths from the considered node v_i to all the other nodes accessible from it.

Example: To provide a concrete example, let us consider the node 0. By observing the values shortest paths shown in [Table 1](#), we consider those referring to paths that go from this node to all others (from 1 to 9) and then we calculate the length (e.g., $d_{0,1}=1$, $d_{0,5}=3$, etc.). By summing them we obtain the value 21 and, by its reverse, the value 0.047619 is obtained for the considered measure.

[Table 3](#) contains the values of Closeness Centrality for each node in G .

By removing the node scoring the highest value of Closeness Centrality, the network would drift, as in the previous case. More in general, by removing the best score nodes according to this measure, the graph would not always be disconnected since in this case the vertices with high centrality value have the meaning of nodes that allow the message to be spread quickly.

Betweenness Centrality

Betweenness Centrality is based on the concept that a v_i node is central if it lies within several shortest paths, or when it takes a strategic role in the network acting as a link for several pairs of nodes. To calculate Betweenness Centrality we refer to the [Formula \(12\)](#), which consists of a simple summation depending on the number of *all pair shortest path* already recalled above.

The complexity of the method is in locating within the graph G all the possible shortest paths. Indeed, for each node of the graph we have to identify all the paths that hold it and sum it up (those paths that do not contain the node considered do not contribute to the summation).

Example: Consider node 6 in G and all the shortest paths between two nodes that contain it: in paths 0 – 9 and 1 – 9 it is present in two of the four possible paths, while in paths 2 – 9, 3 – 9, 4 – 9, 5 – 9 and 7 – 9 it is present in only one of the two possible paths. The result of the sum of the fractions [Formula \(11\)](#) is the value 3.5.

In [Table 4](#) the value of Betweenness Centrality for each node of the graph G is described in increasing order.

By removing from the network only the node with the highest Betweenness Centrality score, the graph would become disconnected as shown in [Fig. 2](#). Again, the node with highest centrality value is node 3.

More in general, by supposing that the communication between each pair of nodes is propagated through the shortest paths needed between them, in most cases if the highest score nodes are eliminated then the message will no longer propagate within the network.

Conclusion

In this manuscript we provided an overview of the most important centrality measures proposed in the literature and applied to biological networks analysis. We distinguished centrality measures based on walks computation from those based on shortest-paths computation. We also provided suitable examples showing how some of the considered measures can be calculated. More specifically, we considered the calculation of Degree, Closeness and Betweenness Centralities.

For all the considered measures, if the node scoring the highest value of centrality is eliminated from the network, then the network may be reduced to a disconnected graph, since that node is a *crucial* node for the links between the knots of the network. After deleting it, the values for each node will change, or most of the power values will be reduced.

However we note that, unlike the small example we proposed in which the node scoring the highest value of centrality is always the same, generally it may not happen and an interesting matter is the comparison of rankings obtained according to different centrality measures.

Introduction

The importance of networks lies in the simple model they represent, which applies to several real-world situations. Essentially, a network is a set of entities linked into a whole uniform structure. We can find examples of systems composed by individuals connected in some form in several situations. We can find (Newman, 2010, Section “Introduction”) lists the most common ones: in biology and bioinformatics for example, networks provide the mathematical representation of connections within biological systems (Barrat et al., 2008, ch.12). Examples of biological networks are: neural networks, connecting neurons in the brain (Bullmore and Sporns, 2009); ecological networks such as the “food web” (Dunne et al., 2002); protein interaction networks, representing interaction between proteins in a cell (Habibi et al., 2014); gene co-expression networks, connecting genes which show similar expression patterns across biological conditions (Weirauch, 2011); gene regulatory networks, describing interactions among molecular regulators (Davidson and Levin, 2005); metabolic networks, describing how the chemical compounds of a living cell are connected by biochemical reactions (Palsson, 2006).

Studying the characteristics of such networks is important because it can unveil their statistical and mathematical properties and ultimately help in making predictions about their structure and dynamics. The networks, we are considering, are complex systems, and hence understanding their topological organization allows to model their behavior.

We will focus on mathematical, statistical and computational tools for analyzing and modeling networks. We will split our dissertation into two articles: the current one will focus on defining fundamental quantitative properties characterizing and describing the underlying structure on a network; the next one is devoted to reviewing the mathematical models which explain such properties and the observations in the real world.

The content of this survey is limited due to the wide nature of the subject. The interested reader can refer to survey article by Strogatz (2001), Albert and Işıl Barabási (2002), Newman (2003) and books by Watts (1999), Dorogovtsev and Mendes (2003), Barrat et al. (2008), Kolaczyk (2009), Newman (2010), Van Mieghem (2014).

Background

We will start by fixing the mathematical notation. Networks are represented by a graph $G = \langle V, E \rangle$, defined by a set V of $N = |V|$ vertices/nodes and a set E of $L = |E|$ edges/links. The graph can be also represented through a $N \times N$ adjacency matrix A , with elements $a_{i,j}$ taking value 1 when there is an edge starting from i to j , and 0 otherwise. When $a_{i,j} = 1$, then j is denoted as an *adjacent* node of i . A *subgraph* G' of G is a graph devised by a subset of the nodes in G : formally, $G' = \langle V', E' \rangle$ where $V' \subseteq V$ and $E' \subseteq E$.

We can devise some properties which characterize a network, as exemplified in Fig. 1:

- Graphs can be *undirected*, if A is symmetrical, i.e., $a_{i,j} = a_{j,i}$ for each i, j . By converse, *directed* graphs assume that $A \neq A^T$.
- Nodes and edges can be associated with properties/attributes, such as e.g., weights. For the edges, weighted links assume the existence of a matrix $W \in \mathbb{R}^{N \times N}$ such that $w_{i,j}$ represents the weight associated with the edge from node i to j .
- Some graphs can admit *self loops*, i.e., the possibility that $a_{i,i} \neq 0$. Also, *multigraphs* admit multiple edges between the same pair of nodes. Graphs without self loops and multiple edges are called *simple graphs*.
- Finally, *hypergraphs* are special graphs where edges can involve multiple nodes. In such case, the adjacency graph can be alternatively represented as an incidence matrix between nodes and edges.

Given a node v , the *degree* K_v of the node is defined as the number of edges reaching i . For directed graphs, we can distinguish K_v^{in} and K_v^{out} , counting the edges where v is the destination or the source, respectively. Within Fig. 1(a), $K_2^{\text{in}} = 1$ and $K_2^{\text{out}} = 2$, whereas $K_2 = 3$ in Fig. 1(b). It turns out that $L = \sum_{v \in V} K_v^{\text{in}} = \sum_{v \in V} K_v^{\text{out}}$ for directed graphs, and $L = \frac{1}{2} \sum_{v \in V} K_v$ for undirected ones. When $K_v = N-1$ for each v , the graph is *complete* and $L = L_{\text{max}} = N(N-1)/2$. From an algebraic point of view, $K_v^{\text{in}} = \sum_{u \in V} A_{u,v}$ and $K_v^{\text{out}} = \sum_{u \in V} A_{v,u}$ (and $K_v = (\sum_{u \in V} A_{u,v}) = (\sum_{u \in V} A_{v,u})$ for undirected graphs). Further, $L = (\sum_{u,v \in V} A_{u,v})$ for directed graphs, and $L = \frac{1}{2} \sum_{u,v \in V} A_{u,v}$ for undirected graphs.

A *path* between u and v is a sequence of adjacent nodes $n_1 \rightarrow n_2 \dots \rightarrow n_k$ such that $n_1 = u$, $n_k = v$ and $n_i \neq n_j$ for each $i \neq j$. If such a path exists, then we say that v is *reachable* from u . Within Fig. 1(a), there's a path between 3 and 4 composed by the sequence $3 \rightarrow 1 \rightarrow 2 \rightarrow 4$ and hence 4 is reachable by 3. The converse does not hold, but it holds for the graph in Fig. 1(b). The *length* of a path is the number of edges traversed by the path. There is an interesting relationship between reachability, length and the powers of A . Clearly, adjacent nodes represent paths of length 1, and the adjacency matrix represents all those paths. It is straightforward to

Fig. 1 Example graphs.

notice that, whenever $A_{u,w} A_{w,v} = 1$, then the path $u \rightarrow w \rightarrow v$ is observable in the network. Thus, for the graph in [Fig. 1\(a\)](#), we can observe that

$$A^2 = A \times A = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \times \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

Within A^2 , the cell (u, v) denotes the number of paths of length 2. In particular, node 1 can reach node 3 through the path $1 \rightarrow 2 \rightarrow 3$ and node 3 can reach node 2 through $3 \rightarrow 1 \rightarrow 2$.

Similarly, as the product $A_{u,w} A_{w,s} A_{s,v}$ denotes the existence of path $u \rightarrow w \rightarrow s \rightarrow v$, A^3 is representative of all the reachability relationships with paths of length 3:

$$A^3 = A^2 \times A = \begin{pmatrix} 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \times \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

where we can observe that there are 4 paths of size 3, respectively $1 \rightarrow 2 \rightarrow 3 \rightarrow 1$, $2 \rightarrow 3 \rightarrow 1 \rightarrow 2$, $1 \rightarrow 2 \rightarrow 3 \rightarrow 1$, $3 \rightarrow 1 \rightarrow 2 \rightarrow 3$ and $3 \rightarrow 1 \rightarrow 2 \rightarrow 4$. In general, the cell (u, v) of A^k denotes the number of paths from u to v traversing k edges.

The distance $d_{u,v}$ between two vertices u and v is the length of the shortest path (also called *geodesic path*) between them.

Basic Tools and Methodology

The study of networks is essentially approached through graph theory (Bondy and Murty, 2008). The advent of large-scale networks has posed some problems which make the traditional approaches to graph theory inadequate to model the nature and complexity of these networks. This has shifted the focus on the analysis of large-scale statistical properties which are better suited to capture in quantitative terms the underlying organizing principles which justify the topology of the network.

When studying the topology of a network, we are mainly interested in investigating the structural properties of the underlying graph. We can summarize these properties in four essential components (Kolaczyk, 2009):

- connection characteristics among vertices;
- routes for movement of information;
- importance of vertices;
- regularities within groups of vertices.

We shall use two real networks as running examples. The first one is a relatively small transcriptional regulatory network of *E. coli* (Shen-Orr et al., 2002), consisting of 423 nodes and 518 edges. The network is represented in Fig. 2(a) and represents direct transcriptional interactions between transcription factors and the operons they regulate (an operon is a group of contiguous genes that are transcribed into a single mRNA molecule). The second dataset represent a network of yeast protein to protein interaction Sun et al. (2003) and it contains 2361 nodes (proteins) and 6646 edges (interactions), Fig. 2(b).

The literature on network science has developed some measures for quantifying network properties. These metrics summarize either local or global topological structures, and characterize either nodes and edges, or network cohesion. Simple global measures include the following:

- The sparsity coefficient

$$\rho = L/L_{max} = \frac{\kappa L}{N(N-1)}$$

where $\kappa=1$ for directed graphs, and $\kappa=2$ for undirected graphs. For the networks of Fig. 2 we have $\rho^{(ecoli)} = 5.8 \cdot 10^{-3}$ and $\rho^{(yeast)} = 2.3 \cdot 10^{-3}$.

- The average degree $\langle k \rangle$,

$$\langle k \rangle = \frac{1}{N} \sum_{v \in V} K_v$$

For directed graphs, the definition adapts to whether we are considering the node as a source or as a destination: $\langle k^{in} \rangle = \frac{1}{N} \sum_{v \in V} K_v^{in}$ and $\langle k^{out} \rangle = \frac{1}{N} \sum_{v \in V} K_v^{out}$. We can easily observe that $\langle k \rangle = \kappa L/N$. It is also worth observing (Newman, 2003) that the definition can be adapted to consider situations where there are nodes which are not connected. For the example networks, we have $\langle k \rangle^{(ecoli)} = 2.45$ and $\langle k \rangle^{(yeast)} = 5.63$.

- The average distance ℓ ,

$$\ell = \frac{1}{N(N-1)} \sum_{\substack{u, v \in V \\ u \neq v}} d_{u,v}$$

The contribution of unconnected nodes is not considered here. For the example networks, we have $\ell^{(ecoli)} = 4.82$ and $\ell^{(yeast)} = 4.38$.

- The size $d = \max_{u, v \in V} d_{u,v}$ of the longest distance in G , denoted as the *diameter* of G .

Among the basic statistics, we can also devise a census of some specific components which characterize the graph. Typical components are *dyads* (pairs of nodes) and *triads*. Fig. 3 shows all the possible dyads and triads which can occur in a network. For example, the dyad census on the *ecoli* network comprises 518 mutual dyads and 88,735 null dyads.

Fig. 2 Example biological networks (node size and color is displayed according to node degree).

Fig. 3 Dyad and Triad census.

An essential tool in the analysis of the topology of a network is the concept of *centrality*, as a measure of the structural importance of an element in the network (Koschutzki *et al.*, 2005). The intuition about a centrality measure is to denote a rank about the importance of vertices or edges of a graph by assigning real values to them.

The simplest form of centrality is *degree centrality* $C_d(v)$, representing the potential of communication among nodes:

$$C_d(v) = \frac{K_v}{L-1}$$

The degree centrality is a local measure, because the centrality value of a node is only determined by the number of its neighbors. In directed networks, two variants can be devised, depending on whether we consider incoming or outgoing nodes.

A natural extension of degree centrality is the *eigenvector centrality* $C_e(v)$, which in a sense weights the importance of connections. It can be defined recursively as the sum of the eigenvector centrality of v 's neighbors:

$$C_e(v) = \frac{1}{\lambda} \sum_{u \in V} A_{u,v} C_e(u)$$

where λ is a normalizing constant. Written in matrix notation, C_e is the solution of the equation $AX = \lambda X$, which suggests that x is an eigenvector of A and λ is the corresponding eigenvalue. Typically, λ is chosen to be the largest eigenvalue of A (Bonacich, 1987). There are several variants of eigenvector, for instance PageRank (Brin and Page, 1998) or hub/authority (Kleinberg, 1999).

Other measures focus on on shortest paths, measuring, e.g., the average distance from other vertices, or the ratio of shortest paths a vertex lies on. These measures give information about the global network structure. *Closeness* centrality represents the potential of independent communication:

$$C_c(v) = \frac{1}{\sum_{\substack{u \in V \\ u \neq v}} d_{u,v}}$$

Nodes with high closeness are considered structurally important, since they can easily reach (or be reached) by other nodes.

An alternative concept is based on the idea that a node is capable of controlling the connections. *Betweenness* centrality measures the extent to which a node is crucial for the connection between any two nodes.

$$C_b(v) = \sum_{\substack{s, t \in V \\ s \neq t \neq v}} \frac{N_{s,t|v}}{N_{s,t}}$$

where $N_{s,t}$ represents the number of shortest paths between s and t , and $N_{s,t|v}$ the number of shortest paths passing through v . The ratio can be interpreted as the probability v is involved into any communication between s and t .

The so far described centrality measures on our two running examples are shown in Fig. 4.

Closeness and betweenness are particularly sensitive to large-scale networks. Their computation is tractable in the conventional sense, i.e., there exist polynomial time and space algorithms able to compute their exact values. Nevertheless, the exact centrality index computation is not practical for graphs with a large number of nodes: real scenarios can reach thousands, millions, even billions of nodes. Recently, approximation algorithms have been investigated (Riondato and Kornaropoulos, 2016; Brandes and Pich, 2007) that trade off accuracy for speed and efficiently compute high-quality approximations of the centrality values.

Assessment of Structural Properties

In this section we consider some basic properties of networks. There are essentially three concepts which characterize complex networks.

Degree Distribution

Recalling that the degree K_v of a node v in a network $G = \langle V, E \rangle$ is the number of nodes incident upon v in E , it is useful to consider the whole set $\{K_v\}_{v \in V}$ and investigate its properties. We can denote by $p_k = \Pr(K_v = k | v \in V)$ the probability that a randomly chosen node in V exhibits degree k . Fig. 5 shows the frequency histograms of node degrees for both *ecoli* and *yeast*.

The degree distribution provides a natural summary of the connectivity within the graph, and it becomes an interesting metric especially for large graphs. Typically, in big networks, the degree distribution of the vertices is right skewed: that is it has a long tail on the values above the mean. Fig. 6 shows the degree distribution for the two datasets, in log-log scale. For the *yeast* dataset, the node degrees range between 0 and 64, and the tail of the distribution is notably noisy, due to the skews on large degrees. We can also observe that the majority of vertices have low degree, and the density tends to decrease exponentially as long as the degree increases.

Such an exponential behavior is typical in large scale networks, and typically the distribution can be characterized as a *power-law* distribution:

$$p_k \propto k^{-\alpha}$$

The log-log plotting has the nice property of highlighting the linear relationship $\log p_k \propto -\alpha \log k$ which derives directly from the functional form of the distribution. Power law distribution has the property that their cumulative counterpart $P_k = \sum_{x=k}^{\infty} p_k$ is

Fig. 4 Distribution of centrality measures.

Fig. 5 Frequency histogram for K in both *ecoli* and *yeast*.

also a power law, with functional form $P_k \propto k^{-\alpha+1}$. Fig. 7(a) shows the fitting of the cumulative distribution for the *coli* network. The fitting holds for $\alpha = 2.39$.

Networks with power-law degree distributions are called *scale-free* networks and have been extensively studied (see e.g., Newman (2005)). There are, however, other common long-tailed functional forms for the degree distributions, such as exponential

Fig. 6 Degree distribution (in log-log scale).

Fig. 7 Cumulative degree distributions and their fits.

or lognormal. **Fig. 7(b)** shows that the *yeast* dataset does not fit a power law: within the graph, the red line shows a lognormal fitting. More complicated models can even exhibit combined distributions, such as mixtures of power-laws ($p_k \propto \sum_k \beta_k k^{z_k}$) or power-laws with exponential truncation ($p_k \propto k^z e^{-\beta k}$).

Small World

The connectivity of a network is usually described by means of paths and connected components. A *connected component* is a maximal subset $S \subseteq V$ where there is a path between any pair of nodes in S . The connected components represent the subgroups.

There is a typical situation which can be observed in the topology of large-scale networks. Notably, a network is characterized by a component which includes a large amount of nodes (the *giant component*), while the rest of the network is made of small components disconnected from each other. This is clearly visible in the networks of **Fig. 2**.

Another feature which characterizes large-scale networks is the small-world phenomenon, i.e., the fact that distances are typically small and consequently ℓ is small as well. For the graphs in **Fig. 2**, we can observe $\ell_{\text{ecoli}} \approx 5$ and $\ell_{\text{yeast}} \approx 4$. Also, **Fig. 8** shows the frequency distribution of the distances in the two graphs. As we shall formally see in a next article, this phenomenon can be mathematically characterized as $\ell \leq C \log N$ for some constant C , as a consequence from the fact that the number of connected nodes grows exponentially as long as the distance grows.

There is a connection among the heavy-tailed degree distribution, centrality of nodes and the small world effect. The fact that there exist few nodes with high connectivity eases the walk-through the network, thus making the geodesic paths shorter. In fact, central nodes are more likely to appear in shortest paths within the network than less important nodes.

Fig. 8 Frequencies of all distances.

Network Cohesion

Another element which characterizes the topology of a network is the cohesion, representing the characterization of the local neighborhood. We have already seen that large-scale networks tend to have a relatively low degree. The question that raises is then: do nodes belong to cliques? A *clique* is a complete subgraph.

There are many ways to quantify network cohesion. However, a common measure is transitivity (or *clustering coefficient*), i.e., the relative number of closed triangles (triads). That is, if vertex u is connected to vertex v , and v is connected to w , then u is also connected to w . Measuring the extent at which this relationship holds provides as with a way of measuring cohesion. Thus, formally the clustering coefficient of a node v can be defined as:

$$C(v) = \frac{2e_v}{K_v(K_v - 1)}$$

where e_v is the number of edges connecting the neighbors of v (for example, $e_v = \frac{1}{2} \sum_{u,w} A_{v,u} A_{v,w} A_{u,w}$ on an undirected graph). The overall clustering coefficient C can hence be devised as the average of $C(v)$ for all v .

Most, large scale networks exhibit a relatively high clustering coefficient: a clear sign that transitive closure holds on a relevant part of the graph. For example, for the networks in Fig. 2, we have $C^{(ecoli)} = 0.02$ and $C^{(yeast)} = 0.10$. To see why these numbers are high, we can compare them to the totally random situation where the number of neighbors is constant and these neighbors are randomly chosen. Then, given two neighbors u, w of v , the probability of them being incident would be proportional to N^{-1} . In the *yeast* dataset, this would correspond to ~ 0.0003 , which is way lower than the actual $C^{(yeast)}$.

Assortativity and Degree Correlation

A further direction worth investigating when analyzing the topology of a large scale network, is to check for *assortativity*, i.e., the tendency of nodes to exhibit a kind of homophily according to a given property. In other words, assortativity measures a non-trivial level of affinity, projected on some features, of connected nodes. For example, in social networks it is common to associate with people who share the same interests or come from the same local community. A high level of assortativity shows a positive correlation between the shared features and the nodes connections (phenomenon called *assortative mixing*), while a low level indicates a negative correlation, i.e., connections are built by nodes which exhibit strong differences in terms of the chosen features (triggering a *dissortative mixing*). Building an *assortativity coefficient* requires several steps (Newman, 2010). First of all, we need to count the edges whose nodes share a feature f :

$$\sum_{edges(u,v)} sim_f(u,v) = \frac{1}{2} \sum_{u,v} A_{u,v} sim_f(uv) \quad (1)$$

where $\frac{1}{2}$ normalizes the double nature of each edge and $sim(u,v) \in [0,1]$ is a similarity function which measures the closeness of nodes u and v according to the feature f . For example, sim can be the Kronecker delta (for discrete features) or the normalized difference (for scalar values).

This quantity does not avoid trivial phenomena, for instance if all the nodes share only one feature its value is maximized, but there is no useful information in it. To balance this issue, we can remove trivial connections generated by a random mechanism, keeping only those connections that are beyond our expectation. The expected number of trivial random affinities is:

$$\frac{1}{2} \sum_{u,v} \frac{K_u K_v}{2L} \text{sim}_f(u, v) \quad (2)$$

where $2L$ is the number of involved nodes for all the edges and $\frac{K_u K_v}{2L}$ is the expected number of edges between nodes u and v . Now, we can define the *modularity* Q of a network as the difference of Eqs. (1) and (2):

$$Q = \frac{1}{2L} \sum_{u,v} \left(A_{u,v} - \frac{K_u K_v}{2L} \right) \text{sim}_f(u, v) \quad (3)$$

The last step is the normalization of the modularity in order to obtain the assortativity coefficient P . The normalization depends on the maximum value of Q , that is reached with a perfect assortative mixed network, where $\text{sim}_f(u, v) = 1$ when $A_{u,v} = 1$:

$$\begin{aligned} P = \frac{Q}{Q_{\max}} &= \frac{\frac{1}{2L} \sum_{u,v} \left(A_{u,v} - \frac{K_u K_v}{2L} \right) \text{sim}_f(u, v)}{\frac{1}{2L} \left(2L - \sum_{u,v} \frac{K_u K_v}{2L} \right) \text{sim}_f(u, v)} \\ &= \frac{\sum_{u,v} \left(A_{u,v} - \frac{K_u K_v}{2L} \right) \text{sim}_f(u, v)}{2L - \sum_{u,v} \frac{K_u K_v}{2L} \text{sim}_f(u, v)} \end{aligned} \quad (4)$$

The so defined assortativity is able to express if connected nodes exhibit a certain level of interest for the same features; an interesting evolution of this concept involves the possibility of measuring if different feature values are correlated among the nodes. Under this perspective nodes with some features try to connect to other nodes which are complementary or simply different: as instance let's think about sentimental relationships among users of a social network, an individual is searching for her better half that may complete her.

Considering assortative mixing characterized by scalar features, we can exploit the covariance concept to formalize the multi-value assortativity:

$$\begin{aligned} \text{cov}(x_u, x_v) &= \frac{\sum_{u,v} A_{u,v} (x_u - \mu)(x_v - \mu)}{\sum_{u,v} A_{u,v}} \\ &= \frac{1}{2L} \sum_{u,v} \left(A_{u,v} - \frac{K_u K_v}{2L} \right) x_u x_v \end{aligned} \quad (5)$$

where x_u (resp. x_v) is the value of the node u (resp. v) for the target feature, and μ the expected value computed as:

$$\mu = \frac{\sum_{u,v} A_{u,v} x_u}{\sum_{u,v} A_{u,v}} = \frac{1}{2L} \sum_u K_u x_u$$

It's simple to notice that Eq. (5) is very similar to Eq. (3) with the product $x_u x_v$ replacing $\text{sim}_f(u, v)$. Hence, its normalization, with the perfect mixing assumption, produces a multi-value assortativity coefficient:

$$P = \frac{\sum_{u,v} \left(A_{u,v} - \frac{K_u K_v}{2L} \right) x_u x_v}{\sum_{u,v} \left(K_u \delta_{u,v} - \frac{K_u K_v}{2L} \right) x_u x_v} \quad (6)$$

where $\delta_{u,v}$ is the Kronecker delta, which is 1 if $u=v$ and 0 otherwise.

A special case of this coefficient is the *mixing by degree*, for studying the *correlation degree*. In a network, the high-degree (resp. low-degree) nodes represent a strongly (resp. poorly) connected component. Since degree is a scalar feature, the mixing by degree multi-value assortativity coefficient can be computed as:

$$P = \frac{\sum_{u,v} \left(A_{u,v} - \frac{K_u K_v}{2L} \right) K_u K_v}{\sum_{u,v} \left(K_u \delta_{u,v} - \frac{K_u K_v}{2L} \right) K_u K_v} \quad (7)$$

where $K_u K_v$ replaced $x_u x_v$ in Eq. (6).

One strong advantage of this formulation is that it requires only to observe the structure of the network and no other information about nodes and edges is needed.

Groups of Vertices

In many real contexts, networks build up in a bottom-up process: single elements (the nodes) group together forming links (edges) according to domain-dependent dynamics and constraints. These groups, actually subgraphs, clusters or communities of nodes, in turn, can join into macro groups in a recursive process that leads to the building of the whole network. Groups can be classified into two categories:

- *Hard clustering*. Nodes are acknowledged to belong to only one group and the group set represents a partition of the node space.
- *Soft clustering*. In this case there is no observable strict partition of the graph, but we can distinguish two scenarios:
 - *Probabilistic clustering*. Nodes are characterized by a probability distribution of belonging to the groups of a finite group set. There is no evidence of a observable membership of the target node to a specific group: this membership is implicit.

- *Fuzzy clustering*. Nodes can simultaneously belong to different groups, i.e., groups can be overlapping. Typically the membership is equipped with a fuzziness score that represents the node's affiliation strength to the group.

In the network analysis research field the discovery of these groups is called *community detection*, which consists in the definition of methodologies and techniques able to locate dense connected (potentially overlapping) components that have low connection with the rest of the network. Detecting communities is a challenging and hard task, since it's difficult to understand what *intra-cluster high connection* and *inter-cluster low connection* mean, and since the number of communities is typically a priori unknown.

In the case of the hard clustering, an interesting approach, that addresses these problems, is to partition the graph where *the observed connection level is lower than the expected one*, in order to find non-trivial separations. This intuition is strictly linked with the *modularity* described in Section Assortativity and Degree Correlation. In fact, modularity measures how many edges fall beyond the expectation between vertices of the same type, see Eq. (3). If we consider as “type” the membership to a community, then connected portions of the network, exhibiting a high modularity degree, actually represent clusters, and a way to detect communities is to look for the partition that generates the highest modularity scores in the network. Unfortunately, modularity maximization is a NP-hard problem (Thai, 2008), therefore, there is space, in this research field, for the definition of heuristic algorithms able to compute a reasonably good approximation of the maximum modularity. A very simple greedy heuristic can be a variant of the (Kernighan and Lin, 1970) algorithm. The technique initially randomly separates the network into two communities, then moves each node from one cluster to the other trying to gain in terms of modularity above a certain threshold. When the algorithm reaches the convergence on the current partition, recursively will focus on the two formed communities. This process will be repeated until no other community can be split.

Closing Remarks

In this article we suggested that the network model can conveniently describe many real world processes. We defined the network model as a graph and provide different metrics to understand and measure features and topology of large-scale graphs. In particular we defined: (i) the centrality measures of the nodes as a relevance score; (ii) the node degree distribution as a tool able to catch the connectivity behavior of the networks; (iii) the node distance, i.e., the capability of information transmission; (iv) the assortativity providing information about nodes' homophily; and (v) communities, groups of strictly connected nodes.

Network Models

Massimo Guarascio, Giuseppe Manco, and Ettore Ritacco, ICAR-CNR, Rende, Italy

Introduction

Networks Science represents a range of techniques and methods for studying large-scale graph-based structures, in terms of the connections established among their entities. These methods span in several application scenarios and allow to understand, explain, describe, and predict the network characteristics. Models for link prediction between unconnected nodes, community/sub-group detection and discovering of interesting structural properties of the network are just some examples.

Understanding the formation and evolution of these networks is a relevant topic for several application scenarios (e.g., *sociology, security, marketing, and human-computer interaction*). In bioinformatics, Network Science is used to study complex biological systems. These systems are dynamic and tend to a quantitative balance between components which often determines biological outcome. Thus, the study of the structural properties can help to understand the cellular behavior from a systems perspective (Eisenberg *et al.*, 2000). In a previous article (Manco *et al.*, 2018), we already listed example biological networks that we recall here: Neural networks (Bullmore and Sporns, 2009); ecological networks (Dunne *et al.*, 2002); protein interaction networks (Habibi *et al.*, 2014); gene co-expression networks (Weirauch, 2011); gene regulatory networks (Davidson and Levin, 2005); metabolic networks (Palsson, 2006).

We also discussed some measurements which characterize essential structural properties of large networks, such as degree distribution, node centrality, network diameter and clustering coefficient. It is natural to ask whether these structural properties are the outcome of the compliance of a network to some mathematical model. Following Kolaczyk (2009), we can roughly describe a network model as a parameter set θ that allows to express the likelihood $\Pr(G|\theta)$ of observing the characteristics of the network G . The choice, of which aspects to model through $\Pr(\cdot)$, expresses the main differences among the various models. For example, the modeling can focus on the static network structures or alternatively on the dynamic processes underlying the network. Besides the justification of static or dynamic properties, network models can also be used for testing purposes. For example, for detecting whether a network significantly differs from a “null” model where it’s not expected to observe specific structural features.

Historically, a reference model was introduced in 1959 by Paul Erdős and Alfred Rényi, where all graphs on a fixed vertex set with a fixed number of edges are equally likely. Starting from there, several forthcoming studies assessed the properties of real networks into formal mathematical models capable of explaining and justifying e.g., “small-world” and scale-free paradigms.

The notion of network model can also be considered in a broader sense: That is, we are also willing to consider models which, although not capable of expressing global properties of the underlying network in a unified way, are nevertheless capable of devising predictive capabilities for specific aspects, such as the formation of a link or the semantic characterization of a node. These models represent the realization of predictive modeling typical of machine learning, in the scenario of network science.

This article is aimed at progressing from the description in Manco *et al.* (2018) by introducing some important reference network models. We classify the models as either descriptive or predictive. The former are aimed at providing a detailed description of the graph or some of its characteristics. For example, models which justify structural features such as degree distribution or the community structure of the network. By contrast, predictive models are aimed at injecting typical predictive modeling tasks such as classification or regression in the context of network science. Thus, the focus in this respect is on models for link prediction or graph classification.

Once again, there is a wide amount of literature in the subject, and the scope of this survey is limited to highlight the key concepts and guide the interested reader to further deepening on the subject. Some reference articles (Albert and Barabasi, 2002; Newman, 2003; Loscalzo and Yu, 2008) and books (Dehmer, 2010; Watts, 1999; Dorogovtsev and Mendes, 2003; Barrat *et al.*, 2008; Kolaczyk, 2009; Newman, 2010; Van Mieghem, 2014) can help in this context.

In the following we adopt the same notation introduced by Manco *et al.* (2018). Just as reminder, we highlight that a network can be represented by a graph $G=(V, E)$, defined by a set V of $N=|V|$ vertices/nodes and a set E of $L=|E|$ edges/links. The graph can be also represented through a $N \times N$ adjacency matrix A , with elements $a_{i,j}$ taking value 1 when there is an edge starting from i to j , and 0 otherwise. When $a_{i,j}=1$, then j is denoted as an *adjacent* node of i . Given a node v , we denote by K_v its degree, and by $Neighbors(v)$ the set of its neighbors.

Descriptive Models

In this section we analyze mathematical models for explaining *structural properties* and *community or subgroup structures*. Structural Analysis of the network aims at understanding how complex networks take place and evolve over time. Typically, the analysis concerns three main aspects: topology of networks, network growth and clustering and partitioning.

Network Models

The simplest mathematical model that we can expect for a network is the the Erdős-Rényi *Random Graph* (Erdős and Rényi, 1959). In this model, the basic assumption is that, by fixing the number N of nodes and the L of edges, edges are randomly placed

between nodes. Specifically, $G(N, L)$, defines an undirected graph involving N nodes and a fixed number of edges, L , chosen randomly from the $\binom{N}{2}$ possible edges in the graph.

An alternative characterization $G(N, p)$ of a random graph with N nodes considers a fixed probability p of observing a link between two nodes, and models the formation of a network as a stochastic process where edges are sampled from all possible pairs according to a Bernoulli trial governed by p . Thus, $G(N, p)$ represents a random graph governed by p where the probability of observing a graph G with L edges is given by a binomial distribution:

$$\Pr(G(N, p) \text{ has } L \text{ edges}) = \binom{\binom{N}{2}}{L} p^L (1-p)^{\binom{N}{2}-L}.$$

The term $p^L (1-p)^{\binom{N}{2}-L}$ represents the probability of observing a specific graph with L nodes. Alternatively, this probability can be specified in terms of the adjacency matrix A :

$$\Pr(A|p) = \prod_{i \neq j} p^{a_{ij}} (1-p)^{1-a_{ij}}$$

The $\binom{\binom{N}{2}}{L}$ coefficient generalizes over all possible configurations with L nodes. **Fig. 1** shows an example random graph and the underlying probability distribution. Notice that the two representations $G(N, L)$ and $G(N, p)$ are equivalent since, within a graph G with exactly L randomly and uniformly chosen edges, the probability of observing an edge is given by $L / \binom{N}{2}$, whereas a random graph with bernoulli parameter p has an expected number of edges given by $L = p \binom{N}{2}$. The latter comes directly from the properties of the binomial distribution.

The important consequences of this extremely simple model is that the most important structural properties can be devised and characterized mathematically.

- The degree distribution is still characterized as a binomial distribution parameterized by p . In fact, a node has the same probability p to connect to any of the other $N-1$ nodes in the network. Thus, the probability $P(k)$ of observing a node with degree k is given by

$$P(k) = \binom{N-1}{k} p^k (1-p)^{N-1-k}$$

As a consequence, the mean degree $\langle k \rangle$ corresponds to the mean value of the binomial distribution: $\langle k \rangle = p(N-1)$. Alternatively, we can assume the mean degree as a constant and devise p from that: $p = \langle k \rangle / (N-1)$.

(a) An example graph with 243 edges.

(b) Graph Distribution. The distribution is centered on $pN(N-1)/2 \approx 247$.

Fig. 1 Random Graphs with $N=100$ and $p=0.05$.

- The clustering coefficient $C(v)$, for a node v , can be estimated by resorting to the underlying distribution. Recall that we have that $C(v) = 2e_v / (K_v(K_v - 1))$ where e_v is the number of connections between the nodes in $\text{Neighbors}(v)$ (Manco et al., 2018). However, in a random graph the expected value for e_v by $E[e_v] = pK_v(K_v - 1)/2$. As a consequence, the expected clustering coefficient is inversely proportional to the number of nodes:

$$C(v) = p = \frac{\langle k \rangle}{N - 1}$$

- It is possible to correlate the presence of the *giant connected component* to the mean degree $\langle k \rangle$. In particular, when $\langle k \rangle < 1$ the graph does not exhibit a giant component, which by the converse can be measured when $\langle k \rangle \geq 1$.
- Since each node can reach on average $\langle k \rangle$ nodes in one step, the average number of nodes that can be reached in d step is given by the geometric series $\sum_{i=0}^d \langle k \rangle^i \approx \langle k \rangle^d$. Hence, a node can reach all the other nodes when $N \approx \langle k \rangle^d$, or equivalently, when $d \approx \frac{\log N}{\log \langle k \rangle}$. This allows to estimate the diameter in terms of the number of nodes.

The shortcomings of the random graph model should be clear so far. Despite the fact that the diameter can be expressed in logarithmic scale of the number of nodes, neither the clustering coefficient nor the degree distribution are realistic when compared to real networks.

Concerning the clustering coefficient, the main problem is the inverse proportion to the number of edges. For example, with reference to the *yeast* network described in Manco et al. (2018), we can observe that $C^{\text{yeast}} = 0.10$ whereas the random graph models would predict $C^{\text{yeast}} = 0.002$. In general, since the mean degree $\langle k \rangle$ can be considered a constant, a random graph generates very small and unrealistic clustering coefficients. This is somehow the effect of mathematical model underlying the probability of a link, which on one side allows for the exponential expansion of the random graph (and as a consequence enables a low diameter), but at the same time does not express any preference for local nodes: Each link is equally likely, whereas instead a small-world model would require that links within a neighborhood should be more probable.

The *Small-World* model (Watts and Strogatz, 1998) is an attempt to cope with this issue, by interpolating between an ordered finite-dimensional lattice and a random graph in order to produce local clustering and triadic closures. The basic intuition is given by the fact that a lattice structure, like the one depicted in Fig. 2(a), exhibits the exact opposite property of a random graph. In fact, in a ring we can establish a priori the number of connections along the ring. The figure shows a ring where each node v has $K_v = 6$. The clustering coefficient turns out to be a constant in this model, since each node exhibits the exact number of neighbors and the number of shared neighbors is fixed as well. For example, for the network in figure we can observe $C(v) = 0.6$ for each v . By converse, average distance ($\ell = 5$ in this case) is affected by the fact that reaching a node requires traversing the ring with a number of hops which is linear in the number N of nodes.

It turns out (Bollobás and Chung, 1988) that adding random edges to a ring can drastically reduces the diameter of the network. In fact, random edges reduce the distances by enabling shortcuts in the paths in the graph. The idea in Small World is to randomly rewiring edges according to a given probability p . The latter can counterbalance the two properties: the lower the value of p , the higher is the clustering coefficient. As a side effect, however, the diameter will result prohibitively high. As p goes from 0 to 1, the construction moves toward a random graph, since the number of edges which are randomly rewired increases. Fig. 2(b),(c) and (d) show how the ring of Fig. 2(a) evolves for increasing values of p . For large graphs, (Watts and Strogatz, 1998) found out that the interval $0.001 < p < 0.01$ guarantees graphs with realistic clustering coefficients and diameters.

The small world model admits several variations: for example in multiple dimensions representing, e.g., geographic distances (Kleinberg, 2000). Still, the degree distribution in this model resembles the binomial distribution of the random graph. The point is that both random graph and small world models assume that the degrees are likely to approach a mean value, and any deviation from this value happens with lower probability. By contrast, real networks exhibit a scale-free degree distribution: Several nodes have low degrees, and higher degrees occur with decreasing probability. The result is that the network exhibit few “hubs”, i.e., node collecting several connections, and the majority of the nodes is instead linked to these hubs. This characterization allows for a viable explanation of the low diameter, since hubs allow shorter connections of peripheral nodes.

A characterization of these properties was given by Barabasi and Albert (1999) in a model which describes network evolution and is called *Preferential Attachment*. The idea behind preferential attachment, originally proposed by Price (1976) is that, whenever a new node is generated in the network, it links to another node with probability that is proportional to its in-degree. The model was proposed for citation networks, where a new node represents a new article and links represents citations. Within the preferential attachment, the citations provided by a new article point to articles which already exhibit a high number of citations.

Mathematically, we can devise a generative process which, starting from an initial graph $G^{(0)}$ exhibiting $N^{(0)}$ nodes and $L^{(0)}$ edges, progressively adds a node v_t for $t \in \{0, 1, 2, \dots\}$. At each subsequent time step t , the node v_t is connected to m nodes already present in $G^{(t)}$, to generate a new graph $G^{(t+1)}$ comprising v_t and the m edges. The probability that the new node is connected to an existing node is proportional to the degree of the latter. In other words, the new node picks m nodes out of the existing network according to the multinomial distribution:

$$p_u = \frac{K_u}{\sum_u K_u}$$

Barabasi and Albert (1999) show that this simple model produces a network where the degree distribution follows a power-law with exponent $\alpha \approx 2.9$. Fig. 3 shows an example network generated according to the above scheme. We can devise, as expected, a

Fig. 2 Small-world graphs and their dependency on the rewiring probability p .

Fig. 3 Barabasi-Albert graph with $N=100$ and $m=1$.

low number of nodes with high degrees, whereas the majority of nodes exhibit $K=1$. This is also witnessed by the degree distribution plotted in the right part of the figure.

There have been several extensions of the basic model illustrated here, which vary from the details in the basic scheme (Albert and Barabasi, 2002). For example, by varying the importance of nodes, by assuming that links can disappear along time, or by adopting a different formulation of the probability to choose an attachment. Also, there has been criticism on the basic idea that

preferential attachment is the main model underlying link formation. For example, one can think of situations, common in biological systems (Vazquez et al., 2003; Solé et al., 2002), where the network grows as a result of node duplication and mutation. The *copying model* assumes a process similar to the one above described for the preferential attachment. However, at time t the connections of v_i are governed by a probability distribution p : With probability p the connections are uniformly chosen among the nodes in $G^{(t)}$, whereas with probability $1-p$ a node s in $G^{(t)}$ is randomly chosen, and a subset of the connections of s are copied as connections of v_i . Notably, this mechanism still produces a scale-free degree distribution and it is more realistic than the preferential attachment in the scenarios of interest for this article.

Besides these classical models, graph modeling can also be considered from a different perspective. We can consider a configuration $C = \{x_1, \dots, x_n\}$ of properties of interest (such as number of edges, centrality measures, etc.) and parameterize the probability of observing such properties in an exponential model. Thus, given a graph G , the probability of observing G with respect to the configuration C can be formalized as

$$Pr(G|C, \Theta) = \frac{1}{Z} \exp \left\{ \sum_i \theta_i x_i(G) \right\}$$

where Z is a normalizing constant, and $\Theta = \{\theta_1, \dots, \theta_n\}$ is the set of parameters which govern the probability of observing the given graph configuration. This general scheme is called *Exponential Random Graph model* (Newman, 2010; Kolaczyk, 2009), and it can be adopted in the traditional statistical setting where the purpose is to fit a parametric model to an ensemble of graphs describing specific properties of interest, rather than the graph as a whole.

Community Structure in Networks

A natural aspect, that several and heterogeneous networks exhibit, is the tendency of forming aggregations of nodes. These aggregations, commonly called clusters, groups or communities, are characterized by some sort of affinity among the nodes forming them and by a refractoriness to familiarize with external nodes. In some cases, communities can be grouped in super clusters in a recursive process that can generate a cluster hierarchy (Flake et al., 2002; Girvan and Newman, 2002). Networks with this behavior are said *modular* or *Small World Networks*.

In the literature, there is no standard definition of community since the concept of “affinity” strongly depends on the target scenario to be analyzed. Node affinity can be translated into similarity (of features, behavior or network topology, e.g., hive swarms), complementarity (e.g., some protein interactions) or shared elements (neighbors, e.g., social networks). In this article we formalize community models based on network topological aspects. An example is shown in Fig. 4, where a graph is partitioned into 4 communities, namely C1, C2, C3 and C4, distinguishable by different colors. As we can see, each community has a high inner level of connectivity, while the connectivity degree with other nodes is poor.

In general we can state that a community defines a group of nodes that exhibit a large number interactions among them with respect the other nodes of the network. This statement can be generalized as follows. Let $G = \langle V, E \rangle$ be a graph and $\delta(V, G)$ be a generic affinity function measuring a score of affinity of nodes in V according to the topology in G , then we define a community as a subgraph $G' = \langle V', E' \rangle$ such that:

$$V' \subseteq V, E' \subseteq E \text{ and } \delta(V', G') > \alpha \cdot \delta(V', G/G'),$$

where G/G' represent the complement of G' with respect to G and $\alpha \geq 1$ is a threshold value expressing how much the affinity within the community must be greater than the affinity with the rest of the graph. Example instantiations of δ are the following.

- Luce and Perry (1949) state that a community is a clique, i.e., a maximal complete subgraph of the network of at least three nodes. Luce (1950) further evolves the previous concept by defining a community as a relaxed variant of *clique*, namely n -

Fig. 4 Communities in a network.

Fig. 5 An example partition into overlapping communities.

clique. A n -clique is a set of nodes in which at least two distinct n -chains exist. A n -chain is a path through the edges of the clique that involves all its n nodes, starting from and finishing on the same node.

- Seidman and Foster (1978) define a community as a maximal k -plex, which, given a positive integer k , is a subgraph of n nodes whose minimal degree is at least $n - k$ (notice that a complete graph is a 1-plex).
- In (Luccio and Sami, 1969) a graph G' is a community in G if, for each subgraph $G'' \subset G'$, such that $\text{terminals}(G'') > \text{terminals}(G')$ where the function $\text{terminals}(H)$ counts the number of paths connecting a generic group H to the nodes not in H . Borgatti et al. (1990) generalize the previous assumption with the property that nodes within a community show a greater edge connectivity with other community members than with external nodes.

Communities have been widely studied in social sciences, but it was in 2002 that the seminal paper by Girvan and Newman (2002) triggered a lot of interest on the problem of community detection. Since then, the problem has been extensively studied, mainly in the physics and in the computer science literature (see e.g., Fortunato, 2010; Xie et al., 2013; Harenberg et al., 2014; Schaub et al., 2017 for an extensive survey). It is important to categorize the approaches to community detection into two classes:

- Approaches which are able to detect non-overlapping communities. These assume that the nodes of the network can belong to a single group, the relation between the nodes is symmetric and no additional information is considered besides the graph structure (Raghavan et al., 2007; Newman, 2004, 2006; Clauset et al., 2004; Zhou, 2003; Richardson et al., 2009). Fig. 4 represent an example of partition into non-overlapping communities.
- By contrast, more recent approaches (Kumpula et al., 2008; Lancichinetti et al., 2008, 2011; Gregory, 2010; Xie and Szymanski, 2012; Chen et al., 2010; Padrol-Sureda et al., 2010) assume that communities can overlap, i.e., that nodes in a network can belong to different communities with different membership levels. Fig. 5 shows an example graph with overlapping communities.

Important examples in biology, where overlapping communities can be extremely useful, are Protein-protein interaction (PPI) networks (Adamcsek et al., 2006; Becker et al., 2012; Mahmoud et al., 2015). Proteins may have different functions in an organism, and typically they participate in a collective action to make a biological process start. A PPI network can be represented by a graph whose nodes are the proteins while an edge indicates a protein collaboration in a same biological process. Within such a scenario, communities represent different biological functions related to overlapping sets of proteins.

Predictive Models

In the previous section, we introduced models of the network characteristics which are capable of explain the real-world observations. The focus in this section is somewhat different. We assume a partial representation of the network graph $G = (V, E)$, and the purpose is to investigate prediction models which are capable of inferring the part of the network which is unobserved. More formally, we assume that each component i (either nodes or subsets of nodes) of the network is characterized by a property X_i , which can be either static or dynamic (i.e., depending from a temporal variable t so that $X_i(t)$ can change through time). For example, a property can be the possibility that an edge exists between a pair of nodes, or the susceptibility of an individual to a given infection. We shall not cover the topic of epidemics in this article (the interested reader can refer to Nowzari et al. (2016); Chen et al. (2013)). Instead, we focus on the topics of link prediction and graph classification.

Link Prediction

Link prediction (Martínez et al., 2016) is a discipline whose aim is to predict the evolution of a network. Specifically, we are interested in predicting which links will form or delete between nodes, by exploiting the network historical data. Within Fig. 6 we can observe how, given a fixed number of nodes, new edges will generate as time goes by: initially, the graph has two connected

Fig. 6 Network evolution. Links among between nodes are continuously generated as time evolves.

Fig. 7 Link prediction: The (C,D) edge is likely to belong to the networks, since all the neighbors of C are connected to D .

components with low global connectivity (**Fig. 6(a)**), then these components connected each other (**Fig. 6(b)**), finally another edge is added incrementing the connectivity (**Fig. 6(c)**).

Biology, biomedicine and bioinformatics have a wide and robust literature in this research area: for instance, [Martínez et al. \(2014\)](#) and [Schwikowski et al. \(2000\)](#) define an automatic technique for predicting interactions. **Fig. 7** shows an example situation where incomplete information is likely to occur, relative to the links in the network. Node C is surrounded by nodes which are all connected to D , and hence it is unlikely that a connection (C, D) won't occur.

To formalize the link prediction problem, we assume that $G=(V, E)$ is the current snapshot of the network. Then, for each pair $x, y \in V$, a *Link Prediction model* can be devised as a function $score(x, y)$, which represents the likelihood that the edge (x,y) should belong to E . Based on the function, G can be updated accordingly, by adding edges with high likelihood and/or removing edges with low likelihood. The specification of $score(x, y)$ falls roughly into one of the following categories: *Deterministic modeling*, *Probabilistic modeling* and *modeling based on supervised/unsupervised learning approaches*.

The idea within deterministic modeling consists in specifying $score(x, y)$ as a similarity score: it is likely that a connection is established between two nodes that are similar, i.e., that share relevant features, interests or objectives, or that exhibit a common behavior. Again, the similarity can be measured *locally* or *globally*, relative to the topology of the network.

- Local approaches define their similarity function observing only the features and the local network topology that are proper of the pair of nodes to rank; no other information is needed. The simplest definition exploits *Common Neighbors* ([Liben-Nowell and Kleinberg, 2007](#)),

$$score(x, y) = |Neighbors(x) \cap Neighbors(y)|.$$

Other variations of this definition are based on *Jaccard Index*, *Mutual Information* ([Tan et al., 2014](#)). The *Adamic-Adar Index*

(Adamic and Adar, 2001) is based on a slightly different definition, which somehow weights the importance of common neighbors:

$$score(x, y) = \sum_{z \in \text{Neighbors}(x) \cap \text{Neighbors}(y)} \frac{1}{\log|\text{Neighbors}(x)|}.$$

Other variations are based on the notions of *Resource Allocation* (Zhou et al., 2009) or *Preferential Attachment* Barabasi and Albert (1999).

- Global approaches exploit the whole network information. In its simplest form, a score based on global information can relate the similarity to the network distance and its variations (Liben-Nowell, 2005): $score(x, y) = d_{x,y}$. More refined proposal, such as the *The Katz Index* (Katz, 1953), weight the length and number of occurrences of a paths:

$$score(x, y) = \sum_l \beta^l \cdot |\text{paths}^{(l)}(x, y)|.$$

Here, β is a constant value and $\text{paths}^{(l)}(x, y)$ is the set of all paths of length l between x and y . *Random Walk models* (Liu and Lii, 2010) are based on the assumptions that a random walk in the network will eventually connect x and y . This entails a recursive definition, where the score depends on the score of the neighbors:

$$score(x, y) = \begin{cases} 1 & \text{if } x = y \\ \gamma \sum_{u \in \text{Neighbors}(x)} \sum_{v \in \text{Neighbors}(y)} score(u, v) & \text{otherwise} \end{cases}$$

where γ represents a normalization constant.

Probabilistic modeling maps the scoring function to the the likelihood of observing the link of interest in a probabilistic setting. In practice, the assumption is that the network is generated through a stochastic model governed by a parameter set θ , to be estimated. In this context, $score(x, y)$ represents the probability $\Pr(x, y | \theta)$ to observe the link (x, y) .

In a sense, the models illustrated in Section “Network Models” propose a way of encoding the above probability. For example, the random graph assumes a constant probability $score(x, y) = p$ for each pair of nodes. Specific instantiations of the exponential random graph model are particularly well-suited to model link prediction, by assuming that the properties of interest are indeed the prospective links. Also, communities can explain link formation by decomposing the probability of a link as the probability that the nodes belong to a given community, multiplied by the probability of observing a link within that community.

More in general, $\Pr(x, y | \theta)$ can be expressed by mapping a set of features $w_{x,y}$ relative to both x and y to a function $g(w_{x,y})$, representing the likelihood to observe these features when x and y are connected. Under this perspective, models based on probabilistic relational modeling (Getoor et al., 2003; Friedman et al., 1999; Heckerman and Meek, 2004; Yu et al., 2006) were also proven suitable for the task of link prediction. Probabilistic Relational Models extend the standard framework of Bayesian Networks by modeling properties and relations between data objects. The framework can be exploited to infer the probabilistic dependencies between properties of nodes and edges connecting such nodes, thus allowing for an effective formulation of the scoring function.

One can also think of specifying $score(x, y)$ as a binary function, and model link prediction as a supervised learning task. In this case, the objective is to specify a classification task which, based on the features $w_{x,y}$ of the prospective (x, y) link, is capable of predicting whether the link occurs. Features can include topological properties and node properties (such as type information, or information content associated with the node). Classification approaches can span from logistic regression to decision trees, SVMs and ensembles (Martínez et al., 2016; Lü and Zhou, 2011; Liben-Nowell and Kleinberg, 2007).

Graph Classification

We conclude this section by briefly mentioning other approaches to supervised learning on graphs. Graph classification can refer two different tasks. A first, intuitive tasks regards the prediction of specific attribute values relative to single nodes of the network. The modeling here resembles the idea of link prediction, where however the prediction of unobserved node attributes is the only goal. Once, again, one can think of formulating a dependency structure among the attributes and with respect of the topology of the network, or include side information which characterize the unknown nodes properties, to be inferred, in terms of the known properties. The probabilistic modeling of Getoor et al. (2003), or even simpler approaches based on standard classification algorithms, can be suitable for these tasks. The challenge here is to encode the information coming from the structure of the neighborhood of the node.

A different task (Tsuda and Saigo, 2010; Rehman et al., 2012; Kong and Yu, 2014) consists in training a model able to predict a class label for a whole graph (Motoda, 2006). This process exploits supervised/semi supervised learning techniques. However, the main issue is how to adapt classical machine learning models to exploit structural and topological information. Essentially, this corresponds to define a mapping function ϕ which encodes a graph G into a relational structure $\phi(G)$, representing a set of features of interest. The features can represent simple properties (Deshpande et al., 2005; Zhu et al., 2012), subgraph patterns (Saigo et al., 2009; Fei and Huan, 2010), or even high-dimensional representations (Gärtner, 2003; Riesen and Bunke, 2009; Schlkopf et al., 2004).

Closing Remarks

In this article we provided an overview of the main network models defined in the field of Network Science for describing and predicting the behavior of large real networks. In particular, we focused on: (i) Mathematical models for explaining structural properties of the network, (ii) descriptive models for detecting relevant groups within the network (communities), (iii) models for predicting properties of entities within a graph, such as unobserved connections/relationships between nodes or node/graph attributes.

Each of these topics exhibits a wide literature and several aspects that, for space reasons, we were not able to cover in this survey. Indeed, the article is meant to provide a basic reference summary for further deepening into the subject. The interested reader is strongly advised to go through the bibliographic references and explore the topics of her interest.

Community Detection in Biological Networks

Introduction

A strong thesis underlying the *systems biology* approach to challenging questions in biology is that such challenges are more likely to be met when framed in terms of (static or dynamic) features of molecular networks. Biological systems and in particular molecular networks allow to uncover emerging phenomena, not evident when interactions among cellular molecular components are considered in isolation. Alternatively, systems and networks can be seen as a suitable tool to model, describe and predict *mesoscale* phenomena, thus providing an essential bridge between the observable phenotypes (e.g. complex traits, diseases and tumors) and molecular “omic” characterizations (e.g. gene mutations, expressed proteins, epigenetic signals). Biological networks describing molecular interactions play a key role in this scenario. We can distinguish two main challenges. The first one is building reliable biological networks from inherently noisy data coming either from direct measurement of interactions, or inferred from indirect evidence. The second challenge is that of using such models (often obtained at a considerable cost) to do meaningful network data analysis leading to the prediction of putative underlying molecular mechanisms. Although several types of networks have been defined and studied in literature, protein-protein interaction networks (PPINs) have emerged at the forefront. This is due to several converging reasons. Firstly, most cell functions are mediated by proteins that cooperate to attain a certain functional effect. Secondly, protein interactions are amenable to cost-effective high throughput assays, thus giving the possibility of building global system-level snapshots of a complete system (often at a cellular level, and beyond). Thirdly, PPINs exhibit strong modularity in a topological sense, that give strong hints of the organization at a functional level. Due to their large size, and importance, PPINs have become the archetypal test case for developing efficient network analysis algorithm, as direct manual inspection of the wealth of accumulated data is next to impossible. Although our survey focusses on community detection for PPI networks, one should bear in mind that several different types of biological networks have been proposed, for which the algorithms included in this survey (or variants thereof) can be applied (Vidal et al., 2011; Gligorić et al., 2015).

Network science is a rich and steady trend of modern research, that draws techniques from fields like mathematics, graph theory, physics, statistics, and computer science (just to name the main sources), and applies them in a variety of fields, including notably the analysis of social, biological and technological networks. Thus, the algorithms described in this survey for community detection in biological networks are built upon a mathematically fertile ground cross fertilized by a large variety of approaches and inspirations.

In the background section, we will mainly recall basic definitions from graph theory underpinning many of the algorithms and methods introduced in the methodologies section. Then, we described the main measures used to assess the quality of the community prediction algorithms. We recall a few notable applications of these methods to large scale projects. Finally, we mention several variations on the theme as well as promising areas of future research, an open questions.

Background

Let $G=(V, E \subseteq V \times V)$ be a simple (undirected) graph (no self-loops, no multiple edges). To be concrete one could think of the nodes in V as molecular species (i.e. proteins, genes, metabolomes) and of the edges in E as evidence of their mutual interaction in the biological process under study. A subset of the nodes $Q \subset V$ induces a subgraph $H_Q=(Q, E_Q)$, where $E_Q=\{(a, b) \in E \mid a \in Q \wedge b \in Q\}$. For a (sub)graph G its *average degree* is:

$$av(G) = \frac{2|E|}{|V|}$$

The *density* of a graph $D(G)$ is the following ratio:

$$D(G) = \frac{|E|}{\binom{|V|}{2}} = \frac{2|E|}{|V|(|V|-1)}$$

which gives the ratio of the number of edges in G to the maximum possible number of edges in a complete graph with the same number of nodes.

A *clique* is a (sub)graph with density 1 (maximum possible value). A k -*clique* is a clique of k nodes. A clique C is *maximal* in G if, $C=V$, or, for any $v \in V \setminus C$, $C \cup \{v\}$ is not a clique in G . Given a parameter $\gamma \in [0..1]$, a γ -*quasi clique* is a graph $G=(V, E)$ such that:

$$\forall v \in V \quad |N_G(v)| \geq \gamma(|V|-1)$$

where $N_G(v) = \{u \in V \mid (u, v) \in E\}$ is the set of immediate neighbors of v in G . Note that v does not belong to $N_G(v)$.

The density of the subgraph induced by $N_G(v)$ is called the *clustering coefficient* of v . A k -core of a graph G is a maximal connected subgraph of G in which all vertices have degree at least k . A vertex v has *core number* (also called *core index*) k if it belongs to a k -core but not to any $(k+1)$ -core. A *core decomposition* of a graph is the partition of the vertices of a graph induced by their core numbers (Seidman, 1983). The *core-clustering coefficient* of a vertex v is the density of the highest k -core in the subgraph induced by $N_G(v) \cup \{v\}$.

Methodologies

Communities in graphs are often defined as relatively dense sub-graphs, thus, many methods for community detection are built upon finding local optima for some density-related function. Here, we list in chronological order important methods built upon this characterization, focussing on the most important steps of each method.

MCode

MCode (Bader and Hogue, 2003) is one of the earliest algorithms explicitly designed to cluster PPI networks. MCode is organized in four phases. In the first phase, each node v is given a weight that is the product of the core-clustering coefficient of v and the maximum value k for which there is a k -core in $N_G(v)$. The nodes are ranked by decreasing values of their weight and used as seeds in this order for the next phase. In the second phase, starting from the unused node highest in rank, MCode adds iteratively neighbors to the cluster being built, provided their weight is above a fixed fraction of the seed's weight. The added nodes are marked as used. In the third phase, clusters that do not include a 2-core are discarded and it is possible to augment the cluster with neighbouring nodes above a certain fixed fraction of the seed's weight. These additional nodes are not marked as used, thus they can be shared among several communities. The final stage computes the largest connected 2-core in each candidate cluster.

C-finder

CFinder (Adamcsek et al., 2006) is a fast program that implements the CPM (Clique Percolation Method) for graph clustering (Palla et al., 2005). The algorithm works in two main phases. The first phase finds all k -cliques in the input network, then CFinder associates two k -cliques if they share a common $(k-1)$ -clique. The clusters produced by CFinder are the equivalence classes of this association relation. Note that the produced distinct clusters may share nodes, and the intersection of two clusters may contain $(k-2)$ -cliques but never a $(k-1)$ -clique. CFinder was one of the first clustering algorithms that could control tightly the overlapping structure of the family of clusters it produces. The parameter k is critical and for biological applications a value in the range $k=4,5,6$ is suggested in the original publication.

CMC

The CMC algorithm (Clustering Based on Maximal Cliques) (Liu et al., 2009) works with edge-weighted graphs. CMC begins by listing all maximal cliques in a graph G by using the algorithm in Tomita et al. (2006), a fast variant of the Bron-Kerbosch method (Bron & Kerbosch, 1973). In the next phase, each maximal clique is given a score that is its average edge weight, and these clusters are ranked by decreasing score value. In the next phase, for each cluster C_i the algorithm considers in turns the clusters C_j of lower score and decides whether to merge C_i and C_j (or remove C_j) based on the relative size of their overlap, and on an weighted inter-cluster score function.

Coach

COACH (Wu et al., 2009) is based on the concept of the *core graph* of a graph $H=(V, E)$. Formally a *core graph* $CG(H)$ is defined as follows. Let's take any vertex $v \in V$ and a vertex u in its neighborhood $u \in N_H(v)$. If the degree of u in the subgraph induced by $N_H(v)$ is larger than the average degree of $G[N_H(v)]$, then u is labeled as a *core vertex*. The core graph of H , $CG(H)$ is the subgraph induced in H by the collection of all the *core vertices* of H for some vertex v (Note that, even if the name is similar, the notion of a *core vertex* in (Wu et al., 2009) is quite different from the notion of core number/core decomposition of (Seidman, 1983) which is based instead on the *minimum degree* of an induced subgraph.)

Given an input PPIN graph G , the algorithm COACH produces first a set of 'preliminary cores'. For each vertex $v \in G$, COACH considers the subgraph induced by $N_G(v) \cup \{v\}$ and computes the core graph of this restricted subgraph. If this core graph is sufficiently dense it is directly the preliminary core of v . Otherwise a greedy procedure is applied to extract from the core graph a sufficiently dense subgraph. After computing a preliminary core for each vertex in G , quasi-duplicates are removed. In the second phase, we add to each preliminary core any node that is linked to more than 50% of the nodes in the preliminary core. Note that both the selected preliminary cores and the preliminary cores augmented with the peripheral nodes may overlap.

SPICi and ClusterOne

Given a PPIN G with edge weights, SPICi (Jiang & Singh, 2010) uses a greedy approach in which nodes of the network are ranked by their weighted degree, and are considered in that order as candidate cluster seeds. A cluster is then expanded starting from a seed by adding the adjacent node with highest connection (by a weighted measure) to the current cluster, while keeping the weighted density above a user defined threshold. The use of advanced data structures to support dynamic graph operations ensures that this method is efficient even for very large graphs.

ClusterONE (Nepusz *et al.*, 2012) is a greedy method similar to SPICi but with significant differences. One difference is that in the cluster construction phase the algorithm uses both expansion and contraction operations. The computed clusters optimize a relative measure of cohesiveness that is essentially a ratio of the internal total weight of a cluster over the total weight of the edges that connect it to the complement graph. More formally, the algorithm evaluates for a set of nodes $V_0 \subseteq V$ the following function:

$$f(V_0) = \frac{w^{in}(V_0)}{w^{in}(V_0) + w^{out}(V_0) + p|V_0|}$$

where $w^{in}(V_0)$ is the cumulative weight of edges within the induced subgraph $G[V_0]$, $w^{out}(V_0)$ is the cumulative weight of edges connecting nodes in V_0 with nodes in $V \setminus V_0$, and $p|V_0|$ is a penalty terms that captures the possibly missing edges in G . The above process is then iterated on the unused node of highest rank elected as the next seed. Finally, in a post-processing phase, highly overlapping clusters are merged, and the candidate list of clusters is returned.

ProRank +

For a given PPIN G ProRank + (Zaki *et al.*, 2012; Hanna & Zaki, 2014) uses several edge pruning and filtering steps before applying a ranking step inspired by the well known Page-Rank algorithm in order to highlight candidate protein seeds, which is the eponymous step of the method.

In detail, the first phase of the algorithm uses the AdjustCD method (Chua *et al.*, 2006) to prune unreliable PPI from the graph G . Moreover three protein types based on local topology (named bridge, fjord, and shore proteins) are identified and removed, since they do not contribute to defining complexes. In the second phase for each pair of nodes the sequence similarity of the corresponding protein primary structure is computed via standard Smith-Waterman scoring. In the third phase a pager-rank-like iterative process that uses the network topology as well as the sequence similarity is applied so to obtain a non-local assessment of the importance of each node.

In the fourth phase, in order of page-rank value, each protein is taken as a seed and considered along with all its neighbors, as a candidate community. These nodes are marked as used and the process iterated with the next highest unused node.

The candidate communities are then filtered by removing almost duplicate communities. Pairs of candidate communities passing a cohesiveness test (similar to the scoring function in Nepusz *et al.* (2012)) are merged together.

Core&Peel

The Algorithm Core&Peel (Pellegrini *et al.*, 2016) works in four main phases. In the first phase, the *Core Decomposition* of the input graph G (denoted with $CD(G)$) is computed, using the linear time algorithm in Batagelj & Zaversnik (2003), giving us the core number $C(v)$ for each node $v \in V$. Moreover, for each vertex v in G the algorithms computes the *Core Count* of v , denoted with $CC(v)$, defined as the number of neighbors of v having core number at least as large as $C(v)$. Next, the vertices of V are sorted in decreasing lexicographic order of their core values $C(v)$ and core count value $CC(v)$.

In the second phase, each node v is considered in turn, in the order given by the first phase. For each v , we construct the set of nodes $N_{C(v)}(v)$ of neighbors of v in G having core number greater than or equal to $C(v)$, and the induced subgraph $G[N_{C(v)}(v) \cup \{v\}]$. We apply some filters based on simple node/edge counts in order to decide whether this subgraph should be processed in the third phase.

In the third phase, we take v and the induced subgraph $G[N_{C(v)}(v) \cup \{v\}]$ and we apply a variant of the peeling procedure described in Charikar (2000) that iteratively removes nodes of minimum degree in the graph. The peeling procedure stops (and reports failure) when the number of nodes drops below the user-defined size threshold q . The peeling procedure stops (and reports success) when the density of the resulting subgraph is above or equal to the user-defined density threshold δ . The set of nodes returned by the successful peeling procedure is added to the set of candidate communities.

In the fourth phase, the algorithm eliminates duplicates and communities completely enclosed in other communities. Also, for pairs of communities very similar to each other as measured by the Jaccard coefficient, the smaller of the two is discarded.

Assessment

In parallel with the development of new methods for community detection, the methodologies for assessing quantitatively the quality of the output have been evolving over time. In particular, as no single score function can be trusted to capture all the aspects of this multifarious problem, often such measures are aggregated together to provide a robust ranking.

Evaluation Measures for Protein Complex Prediction

Li et al., 2010

F-measure: Li et al. (2010) adopted the following f-measure computation to estimate the degree of matching between the found cluster and the gold standard complex. Let P be the collection of discovered clusters and let B be the collection of the gold standard complexes. For a pair of sets $p \in P$ and $b \in B$, the *precision-recall product score* is defined as $PR(p, b) = \frac{|p \cap b|^2}{|p| \times |b|}$. Only the clusters and complexes that pass a $PR(p, b)$ threshold ω (step function) are then used to compute precision and recall measures. Namely we define the matching sets: $N_p = |\{p \in P, \exists b \in B, PR(p, b) \geq \omega\}|$, and $N_b = |\{b \in B, \exists p \in P, PR(p, b) \geq \omega\}|$. Afterwards: $Precision = \frac{N_p}{|P|}$, $Recall = \frac{N_b}{|B|}$, and the *F-measure* is the harmonic mean of precision and recall. (Li et al., 2010) and other authors use $\omega = 0.2$ (or $\omega = 0.25$). Experiments in Peng et al. (2014) indicate that the relative ranking of methods is robust against variations of the value of ω .

Song & Singh 2009

Song and Singh (2009) propose three measures to evaluate the overlap between complexes and predicted clusters: the *Jaccard measure*, the *precision-recall measure* and the *semantic similarity measure*.

Jaccard measure: Let the sets P and B be as above, for a pair of sets $p \in P$ and $b \in B$, their Jaccard coefficient is $Jac(p, b) = \frac{|p \cap b|}{|p \cup b|}$. For each cluster p it is defined $Jac(p) = \max_{b \in B} Jac(p, b)$, and for each complex b it is defined $Jac(b) = \max_{p \in P} Jac(p, b)$. Next, compute the weighted average Jaccard measures using, respectively, the cluster and complex sizes: $Jaccard(P) = \frac{\sum_{p \in P} |p| Jac(p)}{\sum_{p \in P} |p|}$, and

$Jaccard(B) = \frac{\sum_{b \in B} |b| Jac(b)}{\sum_{b \in B} |b|}$. Finally, the *Jaccard measure* is the harmonic mean of *Jaccard* (P) and *Jaccard* (B).

Precision recall product: This measure is computed using exactly the same work flow as *Jaccard*, except that the Jaccard coefficient is replaced with the precision-recall product score used also in Li et al. (2010).

Semantic similarity measure: Let the sets P and B be as above, for a protein x , we define $P(x)$ as the set of predicted clusters that contain x : $P(x) = \{p \in P | x \in p\}$, and $B(x)$ as the set of golden complexes that contain x : $B(x) = \{b \in B | x \in b\}$. Denote with $I(\cdot)$ the indicator function of a set that is 0 for the empty set and 1 for any other set. Let $Bin(\cdot)$ denote the set of unordered pairs of distinct elements of a set. The semantic similarity of p in B is: $Den(p, B) = \frac{\sum_{(x, y) \in Bin(p)} I(B(x) \cap B(y))}{|Bin(p)|}$. Analogously the semantic similarity of b in P is: $Den(b, P) = \frac{\sum_{(x, y) \in Bin(b)} I(P(x) \cap P(y))}{|Bin(b)|}$. Next, we compute the weighted average semantic similarity weighted respectively by cluster and complex size: $Density(P) = \frac{\sum_{p \in P} |p| Den(p, B)}{\sum_{p \in P} |p|}$, and $Density(B) = \frac{\sum_{b \in B} |b| Den(b, P)}{\sum_{b \in B} |b|}$. Finally, the *Semantic Similarity Measure* is computed as the harmonic mean of *Density* (P) and *Density* (B). The semantic similarity measure is the only measure, among those considered in this survey, that puts a premium on correctly guessing the overlap among protein complexes in the golden standard.

Geometric accuracy, sensitivity, and positive predicted value (PPV)

Consider the predicted complexes P and the benchmark complexes B and define the weight $w(p, b) = |p \cap b|$ with $p \in P$ and $b \in B$.

The *Sensitivity* is:

$$S_n = \frac{\sum_{b \in B} \max_{p \in P} w(p, b)}{\sum_{b \in B} |b|}$$

The *Positive Predictive Value* (PPV) is:

$$PPV = \frac{\sum_{p \in P} \max_{b \in B} w(p, b)}{\sum_{p \in P} \sum_{b \in B} w(p, b)}$$

The *geometric accuracy* (Acc) is the geometric mean of S_n and PPV.

$$Acc = \sqrt{S_n \cdot PPV}$$

These three measures are widely used, however it has been noticed that they may produce unreliable scores, when applied to gold standards with highly overlapping communities (see Suppl. Materials in Song & Singh (2009)).

Maximum matching ratio

It is a desirable feature of predicted communities that each community in the reference gold standard is predicted only once. As many quality measures do not reward this property Nepusz et al. (2012) propose a new quality measure: the *maximum matching ratio* (MMR). Consider the predicted complexes P and the benchmark complexes B as nodes in a bipartite graph, where an edge (p, b) with $p \in P$ and $b \in B$ has a weight given by the *precision-recall product score* defined above. A *maximum weighted matching* (Kuhn, 1955) is computed in this bipartite weighted graph that associates at most one prediction to each known complex, while maximizing the weight of the global matching. The MMR is the ratio of the value of the maximum weighted match over the number of complexes in the benchmark (i.e. $|B|$).

Evaluation Measure for Gene Ontology Coherence

Gene Ontology is a well known tool for the functional characterization for proteins. As one expects that predicted clusters exhibit as strong functional coherence, measuring the enrichment of a Gene Ontology class over the predicted clusters is an additional important quality measure.

Formally, let G be a collection of gene ontology annotations, and g one GO class in G , and let M be the set of all proteins. For a predicted cluster p , the *hypergeometric* p-value $H(M, p, g)$ of the association of p to g , when $g \cap p \neq \emptyset$ is:

$$H(M, p, g) = \sum_{i=|p \cap g|}^{\min(|p|, |g|)} \frac{\binom{|M| - |g|}{|p| - i} \binom{|g|}{i}}{\binom{|M|}{|p|}}$$

which represents the probability that a subset of M of size $|p|$ chosen uniformly at random has with g an intersection of size larger than or equal to $|p \cap g|$. As, in general, p will have an hypergeometric score for many gene ontology classes, (Nepusz *et al.*, 2012; Zhang *et al.*, 2008) associate to each cluster p the intersecting gene ontology class of lower p-value. In order to correct for multiple comparisons any version of the Benjamini-Hochberg False Discovery Rate estimation method can be used (Storey & Tibshirani, 2003).

Case Studies

Comparative evaluation of several methods are often found in papers reporting on any new proposed algorithm. However, usually one should pay more attention to third party qualitative or quantitative evaluations, such a those found in Lin *et al.* (2007, 2010), Wange *et al.* (2010), Pizzuti *et al.* (2012), Srihari & Leong (2013), Chen *et al.* (2014), Clancy & Hovig (2014), Pizzuti & Rombo (2014), Srihari *et al.* (2015).

Applications of Community Finding Techniques

Since the turn of the last century several studies have produced comprehensive PPI networks using high throughput proteomic techniques (Gavin *et al.*, 2002; Ho *et al.*, 2002; Von Mering *et al.*, 2002), however in this early stage the extraction of protein complexes, functional modules and pathways from the data was based on direct observation and guided by previous accrued knowledge. Soon after the benefit of a more systematic algorithmic approach to detection/prediction became clear. V. Spirin and L. A. Mirny in their seminal paper (Spirin & Mirny, 2003) study PPI network modularity using three complementary methods. The first method is an exhaustive enumeration of all maximal cliques. The second is application of an early clustering algorithm (Blatt *et al.*, 1996) inspired by a model in statistical physics. The third is a Monte Carlo (MC) simulation aimed at uncovering dense subgraphs of a predetermined size. Gavin *et al.* (2006) use socio-affinity indices to define the weight of edges in the PPIN and then apply iteratively a single linkage hierarchical clustering method to cluster the graph into modules. Both Krogan *et al.* (2006) and by Hart *et al.* (2007) use MCL as main tool to cluster a high quality PPIN graph. Wang *et al.* (2009) develop the algorithm HACO, a variation of the (HAC) Hierarchical Agglomerative Clustering approach, that applies a biologically justified notion of divergence between two clusters. More recently, as richer sets of PPIN were generated, *community detection* methods have been increasingly applied within large scale proteomic studies: MCODE has been used in Li *et al.* (2014) to uncover blood transcription modules (BTM) in a large master network comprising 17,397 genes and 604,363 interactions; and Havugimana *et al.* (2012) use ClusterOne to uncover 622 putative protein complex from a network of high quality of human PPI.

Results and Discussion

Biological Networks

Vidal *et al.* (2011) survey several classes of biological networks: direct interaction networks (metabolic, PPI, gene regulatory) and functional interaction networks (transcriptional profiling, phenotypic profiling, genetic). Many other types of network obtained by heterogeneous data fusion are listed in Gligorić *et al.* (2015). As PPIN constitute the class of biological networks upon which a larger body of knowledge has been built over time, we discuss several trends and problems related to PPIN, although similar issue may arise also for other types of biological networks.

Functional Modules

The notion of a 'functional module' is somewhat general and encompasses a variety of possible schemes and mechanism. For example, a biological pathway (bp), meaning a series of interactions among molecules in a cell that leads to a certain product or a change of status in a cell, as exemplified by, say, the KEGG database (Kanehisa *et al.*, 2011), is a form of functional module where the function is attained by successive protein interactions. On the other side of the spectrum, a protein complex (pc) is also a form

of functional module where the function is attained by a simultaneous interaction of several proteins in an assembled form. Between these two extremes several intermediate configurations can be conceived. In PPIN, a pc may appear as dense subgraphs (for different notions of density), while bp would appear as paths from a trigger protein to one or several target proteins (Pržulj *et al.*, 2004), where in both cases often temporal effects are not encoded in the network. Thus, a notion of functional module based on density may be appropriate for pc detection but may miss pathways or other intermediate notions of functional module, that do not appear to be dense in the chosen graph representation.

Interestingly, several authors have advanced definitions for functional module characterization that use density in a more subtle way. Colak *et al.* (2010) augment the graph $G=(V, E)$, based on PPIN data, with a function $F(\cdot)$ that associates to each vertex $v \in V$ (protein/gene), a gene expression vector $F(v)$ that reflects the expression of v under a variety of conditions and in several tissues, as measured typically in transcriptomic assays. Since F has the structure of a vector space we can define a second graph G_F on the set of vertices V , where two nodes are connected by an edge if the two corresponding vectors are at a distance below a user defined-threshold, under a restricted L_∞ metric. Starting from the intuition that the genes participating in a functional module should have also similar gene expression profiles, the authors aim at finding dense connected bi-clusters, that is subsets $V' \subseteq V$ that induce dense connected subgraphs both in G and in G_F .

Alternatively, Wang & Qian (2013) model functional modules as dense bipartite subgraphs of the master PPIN graph $G=(V, E)$. While a dense bipartite subgraph Q may not be dense in G , in the standard sense, it forms a high weight dense subgraph in the weighted product graph G^2 , where we associate to a pair of vertices $u, v \in V$ the number of 2-paths connecting u and v in G . The authors propose then the algorithm LCP^2 that is an adaptation of the Low Conductance partitioning method in Voevodski *et al.* (2009) when applied to the weighted product graph.

Future Directions

Clustering Versus Community Finding

In this Chapter we have surveyed the basics of community finding in biological networks. Often both clustering techniques (described in Chapter *Cluster analysis of biological networks*) and community finding can be used for the same purpose (e.g. predicting pc in PPIN) and many methods may be considered hybrid approaches, sharing features of both. At a high level clustering techniques are characterized by the minimization of either global objective functions over partitions (e.g. the modularity function) or relative objective functions (e.g. more links inside than outside). At a first approximation, in clustering there is a more complex and subtle competition between modules in order to define their relative boundaries. Community finding instead often try to optimize a simpler local condition (e.g. density above a threshold) and each community is found rather independently from the others. In general, because of this flexibility in the computation, community finding techniques model better overlapping communities. In a practical situation both approaches should be considered and assessed relative to the data and the problem to be solved.

PPIN and Static Data Integration

As PPI networks and the associated analytic tools have been quite successful, there has been much research in methods that retain PPIN as a general scaffold onto which additional biological knowledge is added.

For example, the conservation of protein complexes across species as an additional constraint is studied in Nguyen *et al.* (2013). Jung *et al.* (2010) encode in PPIN the information on mutually exclusive interactions. Proteins in PPIN can also be marked with cellular localization annotations, GO annotations, gene expression, and several types of quality score (Veres *et al.*, 2015). All these aspects are important, and they are possible refinements of the graph model compatible with the majority of the algorithms for finding communities, involving the modelling of additional knowledge in the PPIN framework (see Xu *et al.*, 2013).

This line of research is quite fruitful and still productive, however, it has been pursued often with ad hoc techniques that are difficult to generalize to more than two or three types of data sources simultaneously. As the field of 'data integration' has been attracting attention from different areas, including computer science and computer engineering, it is likely that more robust approaches able to integrate a variety of data sources, could be based on general data integration principles (e.g. that in Žitnik & Zupan (2015)) based on matrix factorization, or on Bayesian inference (Jansen *et al.*, 2003). See also (Gligorićević *et al.*, 2015) for an overview.

PPIN and Dynamic Data Integration

The augmentation of PPIN with dynamic and temporal data deserves a separate treatment from static data integration. While several methods for modelling dynamic behaviour into PPIN have been proposed, the main obstacle to pursuing this line of research appears to be the lack of reliable data. Most high throughput genomic, transcriptomic and proteomic techniques are able to give a snapshot of the status of a cell (or a biological system) at a certain point in time, in a cost effective way. As of now, tracing the evolution over time of the molecular components of a biological system is either confined to few molecules in each experiment, or it is particularly laborious and expensive. Thus, in this area progress may come more readily from new measurement techniques, rather than from a purely "in silico" approach. In particular detecting experimentally the concentrations and

rates of expression over short time ranges is hard and often one has to use simulations instead (Clancy & Hovig, 2014). A line of research has attempted to encode in graph terms timing information modelled in explicit form as time sequences (Mucha *et al.*, 2010; Tang *et al.*, 2011).

Multispecies PPIN

Although PPINs are often built for a single species, data accumulated over time in repositories allows to build multi-species networks (Park *et al.*, 2011; Franceschini *et al.*, 2013), where one connects homologous proteins across different species to form layered graphs. Multi-species PPIN coupled with functional module and pc detection may uncover both conserved module/complexes, but also indicate possible missing edges, and suggest alternative undiscovered control paths by inter-species homology. The issue of evolutionary conservation of features across PPIN is surveyed in Jancura & Marchiori (2012).

PPIN Specialization

The early PPINs were built from one or several biological samples and then all interaction found were merged in a single data structure (PPI integration) thus usually forming a static integrated picture of protein activities in the cell. A recent trend instead aims at building (and analyzing) specialized PPIN that reflect specific conditions. For example tissue and tumor specific PPIN are described in Micale *et al.* (2015). A second line of research tries to take into account internal cellular architecture (e.g. lipid compartment) to refine the spatial resolution of the PPIN (Clancy & Hovig, 2014). In Immunological studies, PPIN representing the immune system response to external agents have been produced (Li *et al.*, 2014). In general this operation can be defined a *PPIN differentiation* as it tries to untangle and control the PPIN response within a specific restricted context (Ideker & Krogan, 2012).

Special Types of Communities

Most community prediction methods in PPIN fail when the protein complex (or the functional module) has features at odds with the assumption of the methods (in particular density and connectivity), thus specialized approaches for small pc and very sparse functional modules (e.g pathways) are needed (Srihari *et al.*, 2015). Although established community finding algorithms handle overlapping modules in a natural way, still finding biologically meaningful overlaps is challenging for more recent approaches (Pizzuti & Rombo, 2014).

The implications of the overlapping of modules on their functionality (competition, cooperation) has not been researched in depth so far. Some preliminary results on sub-complexes and on the characterization of the overall ‘complexome’ are giving some first glimpses on this issue (Zaki & Mora, 2014; Ahnert *et al.*, 2015).

The Complexome

A PPI network is a collection pairwise protein interactions in which communities (complexes, functional units) appear as dense sub-networks. Going one step further several authors (Lee *et al.*, 2011; Clancy & Hovig, 2014) propose the notion of the “complexome” as the study of the organizations of the functional units and complexes within the proteome. In this new scenario, a complexome network is a collection of pairwise functional interactions between pairs of functional units (aka complex-complex networks - CCIN). In this context, it is easier to frame questions relative to transient inter-complex interactions, and take advantage of inter-species evolutionary conservation of complexes functional characterization, even when the proteins involved might not be homologous.

Benchmarking and Resource Portals

PPI detection technologies, database and algorithms have matured in the last few years (Cannataro *et al.*, 2010) and on the side of data several state-of-the-art repositories and databases are available. However, on the side of algorithms the situation is somewhat fragmented. Many sw tools are available for downloading as stand alone applications, some are available via web interface, but many are no longer maintained and hard to find and install. The integrated environment Cytoscape has a number of algorithms available as plugins (Morris *et al.*, 2011), and other methods are available in social network analysis tools (e.g. NetworkX (Hagberg *et al.*, 2008)), and SNAP (Leskovec and Sosis, 2016). Clearly more could be done to offer in an integrated platform a wealth of algorithmic solutions to the problem of community finding in biological networks of several types. There is strong need for standardization in many steps of the analysis pipeline (Goh & Wong, 2016).

Closing Remarks

Searching for communities in biological networks is a fascinating subject of research, in which many different approaches and disciplines contribute original insights. The concept of *community* in a biological network is quite general and flexible but needs to be adapted to the specific biological question to be answered within the system's biology paradigm of network modelling. After

more than a decade of progress, we are probably quite ready for a step forward both in the type and quality of the new (mainly dynamic) of data that can be integrated in the network model, and in the quantitative and qualitative performance of new and improved community finding approaches and methodologies. Here, both the technological advances in high throughput assays and new insights of algorithmic nature will play a leading role.

Introduction

Protein-protein interaction (PPI) databases are key resources for life sciences research, alongside genomic, transcriptomic, and proteomic databases. The importance of PPI databases reflects the fundamental role of protein interactions in cellular processes; almost all cellular activities, such as metabolism, growth, and repair, occur through interactions between proteins. Knowledge of PPIs is essential for understanding phenotypes at a molecular level, including the mechanisms underlying diseases and treatments. Consequently, PPI datasets are used in diverse analytic workflows throughout health science research, including but not limited to discovery of disease genes (Wang *et al.*, 2011), drug discovery (De Las Rivas and Prieto, 2012), and prediction of gene function (Mostafavi and Morris, 2012). Interaction databases facilitate these applications by integrating PPI data from numerous sources, assessing data reliability, providing extensive query capabilities, and returning results in a variety of formats.

Although PPI databases are used in diverse projects, users generally have the same basic requirements: obtaining a high-quality, context-specific PPI network, as easily as possible. A high-quality network should have few false-negatives (i.e., missing interactions) and false-positives (i.e., false interactions), and ideally, should be specific to the conditions being studied (e.g., tissue, disease). The ease of obtaining a network can include factors such as the types of protein (gene) identifiers that can be used for querying the database, available options for filtering results (e.g., by reliability, tissue), and available download formats.

This article reviews how PPI databases meet these requirements, including their approaches for compiling high-quality, context-specific PPI networks and methods for facilitating access to these networks. Strategies for compiling networks include data integration to reduce missing interactions, scoring interaction evidence to reduce false positives, and overlaying networks with gene and protein expression data to provide context. Approaches to facilitate access include multiple options for query IDs, data filters, and download formats. This article provides an overview of these topics, including recent progress and remaining challenges.

Data Integration

Protein-protein interaction data comes from thousands of different studies employing small-scale experiments, high-throughput (HT) screens, and computational predictions to identify interactions. Initially, PPIs were identified in small-scale experiments; studies detected small numbers of interactions and often performed validation by several different bioassays to ensure reliability. Such studies continue to be important and trusted sources of PPI data. Over 38,000 small-scale studies of human PPIs have been published, providing more than 73,000 interactions (Kotlyar *et al.*, 2016).

In the 1990s, high-throughput (HT) screens were developed for detecting many more interactions than small-scale experiments, typically from a few hundred to several thousand. Approximately 400 human HT studies have reported over 210,000 interactions (Kotlyar *et al.*, 2016).

Computational methods began to be used in the late 1990s to predict PPIs. Numerous published prediction methods have reported over 650,000 high-confidence human predicted PPIs (Kotlyar *et al.*, 2016). However, predicted PPIs have not been widely used in health sciences research, despite increasing evidence for their reliability (Elefsinioti *et al.*, 2011; Zhang *et al.*, 2012; Kotlyar *et al.*, 2015).

The creation of PPI databases was driven by the need to integrate numerous disparate sources of PPI data into comprehensive, easily usable PPI networks, a task that is exceedingly difficult for individual researchers working with original PPI publications. Integration is difficult due to several main factors: PPIs are reported in thousands of articles appearing in diverse journals, PPIs and experimental conditions are typically reported as unstructured text, and PPIs may be reported using many different protein and gene identifiers. Overcoming these integration challenges required accomplishing several key tasks: (1) defining a standard data format and a controlled vocabulary for describing PPI detection experiments, (2) establishing accurate mapping between protein and gene identifiers, and (3) curating thousands of journal articles.

Curation is carried out by a number of major databases including BioGRID (Chatr-aryamontri *et al.*, 2017), DIP (Salwinski *et al.*, 2004), IntAct (Orchard *et al.*, 2014), and MINT (Ceol *et al.*, 2010). Many of these databases have been jointly addressing the above challenges, and have formed the International Molecular Exchange (IMEx) consortium (Orchard *et al.*, 2012) to co-ordinate their efforts. Most of these databases obtain all of their data by curating peer-reviewed publications, and are referred to as primary databases (see Table 1). These databases are commonly used sources of data for health sciences research.

Standardizing Data Format and Vocabulary

Data formats and vocabulary for PPI detection experiments were established by the Molecular Interaction (MI) workgroup of the Human Proteome Organization –Proteomics Standards Initiative (HUPO-PSI) (Kerrien *et al.*, 2007). The formats included both

Table 1 PPI databases that include human interactions

Resource type	Resource	URLs	Number of PPIs for <i>Homo sapiens</i>	Inputs	Output – download	PPI annotations
Primary databases	BioGrid (Stark <i>et al.</i> , 2006)	https://thebiogrid.org	312,107	51 Different IDs	PSI-MI, Osprey, delimited text	Score, evidences, modification, phenotype, database

XML (PSI-MI XML) and tab-delimited text (MITAB) (Kerrien *et al.*, 2007). The controlled vocabulary provided an unambiguous way to describe all aspects of a detection experiment, such as the type of detection method and the type of molecular interaction identified (e.g., direct interaction, association) (Kerrien *et al.*, 2007). All major primary databases now use these formats and vocabulary (Orchard, 2012).

Mapping to Common Identifiers

Most current PPI databases uniquely identify interacting proteins using UniProtKB (Consortium, 2017) identifiers. These identifiers can represent not only all full length proteins, but also peptides, fusion proteins, specific isoforms, and proteins whose isoforms are not specified. However, PPI studies and resources sometimes use other identifiers such as gene and protein names, Ensembl IDs (Aken *et al.*, 2016), Entrez IDs (Maglott *et al.*, 2011), RefSeq IDs (Pruitt *et al.*, 2012), and species-specific IDs. Several tools help provide mappings between identifiers (Schmidt and Frishman, 2006; Côté *et al.*, 2007; Huang *et al.*, 2011), but in some cases unambiguous mappings are not possible.

Article Curation

Curation of PPI articles is the most labor-intensive step in PPI data integration. Curation requires extracting information about PPI experiments from unstructured text, and representing this information using a standard vocabulary and format. Several approaches have been considered for performing this task: manual curation by trained biocurators, automated curation aided by text mining, and curation by original authors (i.e., authors of PPI studies curate their own experiments and data). Curation by professional biocurators has provided the best results; automated methods could not achieve the same reliability or level of curation detail (Krallinger *et al.*, 2008; Wang *et al.*, 2016), while curation by authors was unreliable (Leitner *et al.*, 2010), and was not strongly supported by authors (Ceol *et al.*, 2008; Orchard and Hermjakob, 2015). However, manual curation, even by professionals, can be an error-prone (Cusick *et al.*, 2009), difficult, and slow process. Several strategies have been used to make curation easier and more reliable. The IMEx consortium created guidelines for publishing results of PPI experiments (Orchard *et al.*, 2007), to ensure that papers provide necessary, unambiguous information about PPI experiments – thereby improving PPI data and simplifying curation. The IMEx consortium also created guidelines for curation, to clarify the process and encourage consistency. Text-mining methods have been developed to assist curation (Kim *et al.*, 2016). An automated system, the PSI validator (Montecchi-Palazzi *et al.*, 2009), was implemented to check the syntax and semantics of IMEx-compliant curation results. To further ensure reliability, IMEx databases routinely select papers for review by multiple curators (Orchard *et al.*, 2012). These strategies have made curation more reliable, and sometimes easier, but it remains a complex, labor-intensive task. Curating all the published literature with PPI information, and keeping up with new publications presents a daunting challenge. To partially address this problem, IMEx participants have divided the curation workload, each curating a different set of journals (Orchard *et al.*, 2012).

Integrating Multiple PPI Databases and Predicted PPIs

Each major primary database (i.e., whose content is from curation) contains interactions not found in other primary databases. Consequently, obtaining a comprehensive PPI dataset requires content from multiple primary databases. Such comprehensive data can be easily obtained in two ways: from secondary databases (or meta-databases) and from the PSICQUIC service (Aranda *et al.*, 2011). Secondary databases such as APID (Prieto and De Las Rivas, 2006) and PINA (Wu *et al.*, 2009) integrate the contents of multiple primary databases. Some secondary databases such as IID (Kotlyar *et al.*, 2016) and STRING (Szklarczyk *et al.*, 2017) also include predicted PPIs, to provide datasets with more comprehensive proteome coverage. The PSICQUIC interface allows searching multiple PSI-MI compliant databases and returns up-to-date, combined results. Fig. 1 shows an overview of PPI database types and Table 1 provides a comprehensive listing of currently available PPI databases.

Errors in PPI Databases

Sources and Rates of Errors

Errors in a PPI database can be quantified as the false discovery rate (FDR): the fraction of false interactions in the database (i.e., false positives/(true positives + false positives)). False positives in PPI databases (i.e., non-interacting protein pairs) may come from errors in PPI experimental studies or in curation. Quantifying these error rates has been difficult. Error rates of PPI studies depend on how they are estimated – one approach is to retest a subset of detected PPIs by a different assay, but results will depend on the type of assay. Another approach is to compare detected PPIs against previously published PPI datasets, but results will depend on the choice of datasets. Hart *et al.* (2007) calculated FDRs for 7 HT studies as the averages of multiple estimates: resulting FDRs ranged from 35% to 83%. Such different rates can be due to multiple factors including the type of bioassay, the experimental conditions, and the types of proteins being studied. The error rate in curation was estimated at 45% by Cusick *et al.* (2009), based on re-curating some of the interactions in major primary databases. However, the error rates of PPI studies and of curation have

Fig. 1 Types of PPI databases and their sources of data.

likely decreased since the publication of the studies by [Hart et al. \(2006\)](#) and [Cusick et al. \(2009\)](#), due to the introduction of multiple quality control measures.

Improving Data Reliability

To improve reliability, PPI databases have to control errors from two sources – curation and PPI studies. Curation errors have been reduced through quality control measures such as automated syntactic and semantic checking ([Montecchi-Palazzi et al., 2009](#)), and cross-curation ([Orchard et al., 2012](#)), as mentioned in Section Article Curation. The error rate due to PPI studies, as well as curation, can be controlled by assigning confidence scores to interactions and filtering by these scores, although this also reduces the number of returned interactions.

Currently, there is no generally accepted method of calculating confidence scores. Different PPI databases, such as IntAct ([Orchard et al., 2014](#)), iRefWeb ([Turinsky et al., 2014](#)), and HAPPI-2 ([Chen et al., 2017](#)), have different methods of calculating scores. IntAct ([Orchard et al., 2014](#)) scores are weighted sums comprising four types of information: the number of publications reporting the interaction, the number of times the interaction was detected, the types of detection methods (e.g., protein complementation assay, imaging technique), and the types of interactions these methods detect (e.g., direct association, co-localization). Weights assigned to detection methods reflect reliability, while weights assigned to interaction types reflect similarity to direct interaction (i.e., ‘direct association’ receives the highest weight, while ‘colocalization’ receives the lowest). Scores from iRefWeb ([Turinsky et al., 2014](#)), based on the ones proposed by MINT ([Ceol et al., 2010](#)), combine 3 types of information: the number of publications reporting the interaction, the reliability of detection evidence, and the reliability of detection for all orthologous protein pairs. The reliability of detection is a weighted sum across all detections of the interaction; each experiment detecting the interaction has a maximum weight of 1, which is reduced by half if the interaction type was not direct, and further reduced by half if the detection method was a HT screen (i.e., a minimum score of 0.25 is assigned to non-direct interactions, detected by HT screens). HAPPI-2 ([Chen et al., 2017](#)) calculates confidence scores as a product of detection evidence:

$$P_{II} = 1 - \prod_i^N (1 - S_i)$$

where N is the number of different platforms that detected the interaction and S_i is a score between 0 and 1, reflecting the reliability of the platform for detecting direct interactions. For PPIs appearing in a previous version of the database, scores are calculated as:

$$P = 1 - (1 - P_I) \times (1 - P_{II})$$

where P_I is the score from the previous database version, calculated in the same way as P_{II} .

PPI Context

The context of an interaction is the set of conditions in which it usually takes place, including location (e.g., tissue, cell type, sub-cellular localization), time (e.g., developmental stage), and phenotype (e.g., disease state). The set of interactions in a particular context can be very different compared to the full set of PPIs for the organism – for example, some human tissues express less than half of all human genes ([Emig et al., 2011](#)) and additional conditions such as cell type, may further decrease this fraction. Consequently, context-specific PPI networks can have greater efficacy for applications such as identification of disease genes ([Magger et al., 2012](#)).

PPI experiments typically provide limited context information because experimental conditions are often different from an interaction's natural setting (e.g., PPI experiments often use cell lines or yeast cells, very different from a human tissue). However, some aspects of context can be estimated from gene or protein expression, and from protein annotations of disease, function, process, and sub-cellular localization. Several databases including HIPPIE (Alanis-Lobato *et al.*, 2017), IID (Kotlyar *et al.*, 2016), MyProteinNet (Basha *et al.*, 2015), and TissueNet (Barshir *et al.*, 2013), provide tissue-specific interactions by integrating PPIs from primary databases, and identifying a subset of PPIs whose proteins or encoding genes are expressed in the tissue. HIPPIE (Alanis-Lobato *et al.*, 2017) and MyProteinNet (Basha *et al.*, 2015) associate PPIs with sub-cellular localizations based on annotations of interacting protein pairs. HIPPIE (Alanis-Lobato *et al.*, 2017) also associates PPIs with diseases using a similar approach.

Database Functionality

In addition to preparing interaction data, PPI databases also provide extensive functionality for querying, and in some cases analyzing and visualizing interactions. The overall aim is enabling easy retrieval of relevant interactions. A typical use case could be a researcher seeking interactions for a set of mutated genes, and requiring some of the following functionality: querying the database using Ensembl gene IDs, retrieving all detected and predicted partners of the corresponding proteins, filtering retrieved interactions by reliability and tissue, downloading results in an Excel-compatible format, and visualizing the resulting network. This example highlights important types of functionality that users may need: queries by various gene and protein IDs, retrieval of comprehensive networks, filtering of interactions (e.g., by reliability or context), and export of results in convenient formats for further analysis and visualization. The sections below describe support for this functionality among PPI databases (Table 1).

Most PPI databases accept queries by UniProt IDs and many databases accept a wide variety of other identifiers. However, submitting a large set of query IDs other than UniProt can be difficult. Some databases do not support queries by multiple IDs, but a more common problem is that identifiers may not have 1:1 mappings to proteins. If an identifier maps to multiple proteins, users may be asked to select their intended mapping, which can be time consuming if there is a large number of query IDs.

Comprehensiveness of retrieved networks varies greatly between databases; for example, the number of human interactions in major PPI databases ranges from a few thousand to more than two million. Primary databases tend to have fewer interactions than secondary databases, and the largest networks are provided by databases that include detected and predicted PPIs. However, predicted PPIs such as those in STRING (Szklarczyk *et al.*, 2017) may be mostly functional interactions rather than direct or physical associations. Most PPI studies predicting direct or physical associations have not yet been integrated into any secondary databases.

Interactions may need filtering by reliability, context (e.g., tissue, disease state), interaction type, and other criteria. Some primary and many secondary databases enable filtering by confidence scores. Filtering by location is supported by several secondary databases including HIPPIE (Alanis-Lobato *et al.*, 2017), IID (Kotlyar *et al.*, 2016), MyProteinNet (Basha *et al.*, 2015), and TissueNet (Barshir *et al.*, 2013). Filtering by interaction type and other criteria is supported by BioGRID (Chatr-aryamontri *et al.*, 2017), HIPPIE (Alanis-Lobato *et al.*, 2017), and iRefWeb (Turinsky *et al.*, 2014).

Retrieved interactions can usually be downloaded as delimited text files, such as the MITAB files supplied by IMEx databases. IMEx databases and STRING also provide PSI-MI XML files. Several databases including BioGRID, HIPPIE, IntAct, and STRING also provide downloadable formats for network visualization.

Future Directions

In the near future, PPI databases may need to accommodate vast amounts of information related to isoform-specific, mutant-specific, and context-specific interactions. Most PPI studies have not considered how (or whether) isoforms, mutations, or context, affect interactions. However, recent studies (Yates and Sternberg, 2013; Petschnigg *et al.*, 2014; Yang *et al.*, 2016; Naro *et al.*, 2017) suggest that these factors have profound effects on interactomes. Non-synonymous single nucleotide polymorphisms have been shown to alter PPIs (Yates and Sternberg, 2013) and Petschnigg *et al.* showed that mutations of EGFR could substantially alter its interactions, including gains and losses of interaction partners (Petschnigg *et al.*, 2014). Recently, Yang *et al.* showed that pairs of protein isoforms shared less than 50% of their interactions (Yang *et al.*, 2016).

Given the ubiquity of polymorphisms, mutations, and alternative splicing in eukaryotic proteomes, these factors could profoundly impact our understanding of interactomes – not only greatly increasing the number of interactions but also highlighting the importance of context-specific interactions. These factors suggest that individuals, diseases, tissues, and other contexts are characterized by important interactome differences.

PPI databases may soon need to accommodate a huge increase in interactome complexity. This will include supporting queries by specific polymorphisms, mutations, and isoforms, and linking these variants to diseases, tissues and other contexts. Interactions currently stored in PPI databases will benefit from being described in terms of these properties (e.g., detected protein pairs mapped to specific isoforms, PPIs increased/decreased by specific mutations, etc.).

Closing Remarks

PPI databases have become major resources for molecular and systems biology, alongside genomic and proteomic databases. However, PPI data, perhaps more than other data types in systems biology, is scattered across a very large number of studies and is investigated by a great variety of experimental and computational methods. Consequently, PPI databases have undertaken large scale integration efforts including curating thousands of journal papers, creating a controlled vocabulary for describing PPI experiments, and defining common formats for PPI data. At the same time they have introduced quality control measures for curation, methods for scoring interactions, and approaches for associating interactions with context. Through these efforts, PPI networks have become a key resource for tasks such as prediction of gene function, identification of disease genes, and drug discovery.

Biographical Sketch

Max Kotlyar, PhD Max Kotlyar is a research associate at University Health Network, specializing in computational biology. He completed his PhD at the University of Toronto, in the department of Medical Biophysics. His research focuses on computational approaches for identifying protein-protein interactions, disease biomarkers, and drug or alternative therapies from high-throughput biological datasets. His interests include data-mining, machine learning, and network-based methods for analyzing high-dimensional datasets, especially in systems biology.

Chiara Pastrello, PhD Chiara Pastrello is a research associate at University Health Network, Toronto. She is interested in cancer genetics and epigenetics, that she formalised in her medical genetics residency – focusing on the prediction of pathogenicity of unclassified variants in mismatch repair genes. She is further interested in cancer systems biology, specializing in network analysis, and the curation of expression data for multiple databases maintained at Prof. Jurisica lab. Her current research interests include the study of microRNAs in cancer signalling to distant metastasis, as well as the application of network analyses to study molecules and pathways playing a central role in cancer.

Andrea E.M. Rossos is a third-year undergraduate student in a Bachelor of Science program in Honours Biology at McMaster University. She was a Princess Margaret Summer Student who has worked in the Jurisica Lab for summer 2016 and summer 2017 as a recipient of the Ian Lawson Van Toch Internship Award in Cancer Informatics. Andrea has been involved with data curation and development for projects such as microRNA Data Integration Portal (mirDIP), Cancer Data Integration Portal (CDIP) and Arthritis Data Integration Portal (ADIP). She has also been involved with projects looking at the properties and diversity of biomolecule (miRNA, protein, etc.) databases. Her's current research interests are the prognostic and diagnostic roles of microRNAs and other biomolecules in cancer and disease.

Igor Jurisica, PhD I. Jurisica is Tier I Canada Research Chair in Integrative Cancer Informatics, Senior Scientist at Krembil Research Institute, Professor at University of Toronto and Visiting Scientist at IBM CAS. He is also an adjunct professor at the School of Computing, Pathology and Molecular Medicine at Queen's University, Computer Science at York University, affiliate scientist at the Institute of Neuroimmunology, Slovak Academy of Sciences, and an Honorary Professor at Shanghai Jiao Tong University. Since 2015, he has also served as Chief Scientist at the Creative Destruction Lab, Rotman School of Management. He has published extensively on data mining, visualization and cancer informatics, including multiple papers in *Science*, *Nature*, *Nature Medicine*, *Nature Methods*, *J Clinical Oncology*, and has over 11,167 citations over the last 5 years. He has been included in Thomson Reuters 2016, 2015, 2014 list of Highly Cited researchers, and The World's Most Influential Scientific Minds: 2015, 2014 Reports.

Introduction

Protein molecules are the workhorses of the cell, performing and controlling almost all activities in an organism. Although some proteins may work alone, proteins usually collaborate with others to achieve their intended tasks. When proteins work together, the influences and interactions among them can be shown in terms of a graph. The human cell produces potentially 100,000 different proteins, where a gene may produce more than one protein. The interactions among these proteins are responsible for many physiological activities in the body. Organisms vary in the number of their proteins and the number of interactions. Proteins and protein interactions of a large number of organisms are being determined and are recorded in databases. According to one study (Stumpf *et al.*, 2008), humans have 10 times more protein interactions than the fruit fly and 20 times more than the single-celled yeast. A simple but useful approach to viewing such a complex biological system is to represent it as a network of interplay among the different molecules.

Thus, complex systems like Protein-Protein Interactions (PPI) are usually studied computationally from a graph theoretic perspective. Studies suggest that PPI networks (PIN) are conserved through evolution (Sharan *et al.*, 2005). Highly connected proteins within a network are vital molecules and have been found to be more essential for survival than proteins with lower connectivity (Jeong *et al.*, 2001). As a result, the interactions between protein pairs, as well as the overall composition of the network, are important for the overall functioning of an organism. Understanding conserved substructures through comparative analysis of these networks can provide insights into a variety of biochemical processes. The ultimate goal of network alignment is to transfer knowledge of protein function from one species to another. Since sequence similarity metrics such as BLAST bit scores (Altschul *et al.*, 1990) are not conclusive evidence of similar function, the purpose of aligning two PPI networks is to supplement sequence similarity with topological information so as to identify orthologs as accurately as possible.

PIN alignment is a relatively young research area, and successes of PIN network alignment, so far, include uncovering large shared sub-networks between species as diverse as *S. cerevisiae* and *H. sapiens*, and reconstructing phylogenetic relationships among species based solely on the amount of overlap discovered between their PPI networks (Kuchaiev *et al.*, 2010; Kuchaiev and Pržulj, 2011). Comparing two or more biological networks is a particularly challenging problem, since many interesting questions we might ask of these networks are computationally intractable to answer (Atias and Sharan, 2012). Assuming we have k graphs and each graph has n nodes (in reality, it is likely that the graphs have unequal number of nodes), each match tuple a_i contains k nodes, one from each graph. Ideally, we should have n such tuples in the overall alignment A with the stipulation that an alignment metric value is optimized. This is a very complex optimization problem which is NP-complete, and thus, all approaches have to be heuristic. Most papers in the literature report promising results in creating alignments that show either large regions of biological, or of topological similarity between the PPI networks of various species, but few do both well.

We introduce the PIN alignment problem followed by a brief discussion of various aligners proposed to address the issues of pairwise alignment as well as multiple alignment of PPI networks. The quality of alignments needs to be assessed using validation measures. We discuss some of the assessment matrices used for evaluating alignment results.

Protein-Protein Interaction (PPI) Network

The physical interaction between a pair of protein molecules takes place because of biochemical activities within a cell. The synthesis of a protein may also be regulated by another protein. When proteins work together, the influences and interactions among them can be shown in terms of a graph (Braun and Gingras, 2012). A graph showing interactions among proteins in a single species is called a Protein-Protein Interaction network (or map). In a PPI network, the proteins are nodes and molecular interactions between them are edges.

Definition 1: (*Protein-Protein-Interaction Network*). A set of proteins $\mathcal{P}$ forms a PPI network $\mathcal{G} = \{\mathcal{P}, \mathcal{T}\}$ by virtue of the physical interactions among the protein molecules in $\mathcal{P}$ due to various biochemical events. $\mathcal{T}$ represents the set of interactions between a pair of proteins P_i and $P_j \in \mathcal{P}$.

The interaction between a pair of protein molecules is measured using a variety of assays, such as immunoprecipitation, tandem affinity purification, and the yeast two-hybrid approach. Recently, these techniques have been scaled up to measure

Table 1 A summary of few PPI databases

Sl. No.	Database	No. of species	No. of interactors	No. of interactions	Link

interactions on a genome-wide level (Uetz *et al.*, 2000). High-throughput techniques have also been developed to systematically identify protein complexes using affinity purification techniques, followed by mass spectrometry (MS/MS) to sequence the protein (Ho *et al.*, 2002; Gavin *et al.*, 2002).

PPI networks have been built for many different species based on interactions discovered and published by researchers. For example, the BioGRID database currently includes interactions, chemical associations, and other details from 58,254 publications. The total number of non-redundant interactions in the database is 1,110,310, covering more than 60 species. A number of available PPI database sources are shown in Table 1.

Assessment Methods

As the optimal solution is unknown for alignment of real PPI networks, there should be a method to evaluate various results extracted using different aligners. Two collections of evaluation metrics are used to evaluate the quality of alignments. The first set assesses the quality of the topological characteristics of the alignment. The second set measures the essence of the alignment considering biological fit. In this section, we review the evaluation metrics used for PPI network alignment, considering their strengths and deficiencies.

Topological Assessment

Edge correctness (EC)

Edge Correctness (EC) is the most popular metric used to measure the topological quality of network alignments. EC calculates the percentage of edges in the first network that are mapped to edges in the second network (Kuchaiev *et al.*, 2010). EC can be formally defined as

$$EC(G_1, G_2, f) = \frac{|f(E_1) \cap E_2|}{|E_1|} \quad (1)$$

where G_1 and G_2 are the two networks to be matched, and f is the alignment function (Kuchaiev *et al.*, 2010).

It is crucial to realize that an EC of 1 does not necessarily reflect a perfect alignment. In some cases, two different possible network alignments may have the same EC, but one of the alignments is clearly better than the other (Patro and Kingsford, 2012; Milenković *et al.*, 2013). For example, any sparse section in the first network can be easily mapped to a dense part of the second network, although this alignment is not the best match that can be extracted.

Induced conserved structure (ICS)

Recently, to overcome EC's weaknesses, the Induced Conserved Structure (ICS) score has been introduced (Patro and Kingsford, 2012). To circumvent aligning nodes from the first network to dense regions of the second network where opportunities for aligning in different ways are high the ICS score penalizes such an alignment whereas EC does not. ICS is formally defined as

$$ICS(G_1, G_2, f) = \frac{|f(E_1) \cap E_2|}{|E_{G_2[f(v_1)]}|} \quad (2)$$

where $|E_{G_2[f(v_1)]}|$ denotes the total number of edges in the induced sub-network of G_2 that includes all nodes that have been mapped to by f . Therefore, if the number of edges in the subgraph of G_2 induced by the nodes mapped from G_1 , is larger than the number of edges in G_1 , the ICS of the alignment will be lower.

Symmetric substructure score

While ICS addresses an essential weakness in EC by penalizing sparse-to-dense alignments, it does not similarly punish dense-to-sparse alignments. To improve this, the Symmetric Substructure Score, or S^3 was introduced (Saraph and Milenkovic, 2014), to penalize sparse-to-dense and dense-to-sparse alignments equally. In metaheuristic aligners, this metric has been shown to be a more reliable predictor of correct alignment than EC and ICS; it has been found that metaheuristic aligners can increase ICS by minimizing the denominator without increasing the numerator (Saraph and Milenkovic, 2014). S^3 addresses this problem. S^3 is defined as

$$S^3(G_1, G_2, f) = \frac{|f(E_1) \cap E_2|}{|E_1| + |E_{G_2[f(V_1)]}| - |f(E_1) \cap E_2|}. \quad (3)$$

The denominator of S^3 can be thought of as the number of unique edges in the composite graph resulting from overlapping the graphs G_1 and G_2 according to the alignment f .

Largest common connected sub-component

The size of the Largest Common Connected Sub-component (LCCS) considers large connected sub-graphs to be desirable (Kuchaiev et al., 2010). High EC, ICS, or S^3 scores do not necessarily reflect that the aligned nodes form a connected substructure.

Node correctness and interaction correctness

Two other evaluation metrics that have been used require that the true alignment of two PPI networks is known in order to estimate the quality of the extracted alignment. If the true alignment is g , then *Node Correctness* (NC) is the percentage of nodes aligned correctly. Formally, NC is defined as

$$NC(G_1, G_2, f) = \frac{|u_i : f(u_i) = g(u_i)|}{|V|} \times 100 \quad (4)$$

where $u_i \in V_1$, $f(u_i)$ is the mapping of an aligned node using the proposed alignment, and $g(u_i)$ is the correct match. Interaction Correctness (IC) is defined similarly as the percentage of interactions (i.e., edges) mapped correctly (Milenkovic et al., 2010).

As discussed above, NC and IC are measures that require advance knowledge of the true alignment of the networks, which is often unknown, especially for real biological networks. These two tools have been used on both synthetic networks, created for network alignment benchmarking (Sahraeian and Yoon, 2012b), and in noisy self-alignment experiments, where a network is mapped to a version itself that has been corrupted with extra edges (Kuchaiev et al., 2010).

Biological Assessment

Assessing alignments based on topological quality is not always sufficient, especially given the limitations of the topological measures surveyed above. Evaluating alignments based only on topological measures does not mean that the quality of the alignment is certainly good. Preferably, the alignment should be evaluated so as to confirm that the aligned proteins correspond to evolutionarily conserved functional modules. Biological measurements evaluate the alignment's quality with respect to the functional similarities between the two nodes (proteins) that are mapped to each other.

Gene ontology

Alignment papers typically use Gene Ontology (GO) annotations (Ashburner et al., 2000) to judge the functional similarity of aligned nodes. Gene ontology annotations for each protein are collected, and compared to see if they represent similar functions.

It is important to notice that most GO-derived metrics ignore the hierarchical structure of the Gene Ontology (Patro and Kingsford, 2012). Furthermore, many GO terms are assigned based on sequence homology (Pal, 2006). These two factors may generate misleading results if not accounted for (Patro and Kingsford, 2012). It is necessary to keep these two concerns in mind when considering GO-based evaluation metrics.

The naive way for evaluating GO term overlap, which is used by several studies, is to directly report the percentage of aligned pairs of proteins in the alignment that share more than k GO annotations (Kuchaiev and Pržulj, 2011; Memišević and Pržulj, 2012; Neyshabur et al., 2013). This evaluation is very straightforward and easy to interpret, but more sophisticated evaluation approaches have been proposed, as well.

Resnik's semantic similarity

The hierarchical structure of the GO ontology has been considered in computing similarity (Patro and Kingsford, 2012). Resnik's semantic similarity measure (Resnik, 1995; Pesquita et al., 2009), one of the most common ontological similarity metrics that considers hierarchical structure, has been used to design a biological metric for evaluating biological network alignments (Patro and Kingsford, 2012). If the Resnik ontological similarity of two proteins, u and v , is given by $Sim_{Resnik}(u, v)$, the Resnik similarity of aligned networks G_1 and G_2 , using the scoring function f is defined formally as

$$S_{Resnik}(G_1, G_2, f) = \frac{1}{|V_1|} \sum_{u \in V_1} Sim_{Resnik}(u, f(u)). \quad (5)$$

Gene ontology consistency

Another biological metric is Gene Ontology Consistency (GOC) (Aladağ and Erten, 2013), which uses GO annotations to assess of the alignment quality. GOC is a Jaccard index on sets of GO annotations, defined formally as

$$GOC(G_1, G_2, f) = \sum_{(u_i, v_j) \in a} \frac{|GO(u_i) \cap GO(v_j)|}{|GO(u_i) \cup GO(v_j)|} \quad (6)$$

where u_i, v_j are two nodes matched in the alignment of G_1 and G_2 , where a and $u_i \in V_1, v_j \in V_2$. The set of GO annotations of a protein u is expressed by $GO(u)$. This is typically limited to GO terms at depth 5 of the ontology, to avoid issues emerging from annotations of differing specificity.

Normalized gene ontology consistency

NGOC (Elmsallati et al., 2016) improves the evaluation of PPI network alignment for biological fit by taking into account the total number of proteins aligned. As some aligners fail to map all nodes, it is not appropriate to measure the quality of the biological similarity of the resulting alignments using the evaluation metrics mentioned above, especially GOC. As all biological evaluation metrics sum the score of the aligned nodes, an alignment may be better by simply mapping more proteins than in other alignments.

For example, say that aligner A aligns 4000 pairs of nodes and has a GOC score of 234.00, and aligner B aligns 2500 pairs of nodes and has a GOC score of 197.00. In this case, it is not fair to make a decision, based only on the GOC score, stating that aligner A is better than aligner B . Using NGOC, the biological similarity score is divided by the total number of nodes to make a more balanced comparison. According to our example, aligner B is better than aligner A in this case as aligner B scores 0.0788 while aligner A scores only 0.0585.

The NGOC is formally defined as:

$$NGOC(G_1, G_2, f) = \frac{1}{n} \left(\sum_{(u_i, v_j) \in a} \frac{|GO(u_i) \cap GO(v_j)|}{|GO(u_i) \cup GO(v_j)|} \right) \quad (7)$$

where a is the alignment to be evaluated and n is the total number of proteins aligned.

Aligning PPI Networks

PPI network alignment is a relatively new research area. The goal is to uncover large shared subnetworks between species, and derive phylogenetic relationships among species by examining the extent of overlap exhibited by different PPI networks (Vijayan et al., 2015; Milenković and Pržulj, 2012). The abundance of large PPI networks in various publicly available databases presents new opportunities and challenges. Discovering phylogenetic relationships across species by taking into account protein interactions during evolution is a fundamental task in comparative systems biology (Tatusov et al., 1997).

Comparative analysis of PPI networks across species helps identify evolutionary conserved subnetworks. It is often considered a graph alignment problem where proteins from different species are superimposed on one another based on evidence accrued from high protein sequence similarity as well as high topological similarity.

Definition 2: (PPI Network Alignment). Given k distinct PPI networks $\mathcal{G}_1 = \langle \mathcal{P}_1, \mathcal{J}_1 \rangle, \mathcal{G}_2 = \langle \mathcal{P}_2, \mathcal{J}_2 \rangle, \dots, \mathcal{G}_k = \langle \mathcal{P}_k, \mathcal{J}_k \rangle$ from k different species, the PPI alignment problem is to find a conserved subnetwork, A , within each of the k graphs. The alignment graph $\mathcal{A}$ is a subgraph consisting of nodes representing k similar proteins (one per species), and edges representing conserved interactions among the species. Each alignment $\mathcal{A}_i$ can be represented as:

$$\mathcal{A}_i = \{ \langle p_{1i}, p_{2i}, \dots, p_{ki} \rangle | p_{ji} \in \mathcal{P}_j \}. \quad (8)$$

The alignment problem looks for optimal set $\mathcal{A}(\mathcal{G}_1, \dots, \mathcal{G}_k) = \{ \mathcal{A}_i \}_{i=1 \dots k}$ alignments by maximizing the coverage of vertices from all the participating networks.

Comparing biological networks is a challenging problem, since conserved subnetworks are expected to possess both topological and biological similarities. Alignment of a pair of candidate proteins (or a set of k proteins) needs to satisfy certain similarity criteria based on functional and topological mapping as described below.

Functional Mapping

PPI alignment methods often align networks with the help of extra biological information such as the amino acid sequences of proteins, expression levels of corresponding genes, and Gene Ontology terms describing gene relationships and functional annotations. This biological information is used by the aligner to discover more biologically meaningful conserved subnetworks. However, studies have shown that high sequence similarity, determined by programs such as BLAST (Altschul et al., 1990), do not always result in similar protein functions (Elmsallati et al., 2017).

Topological Mapping

Some aligners use only network topology or structure of the network to align the PPI networks. Similarity between the nodes or proteins is calculated using a topological similarity score based on the structure of the PPI networks. Network structure related characteristics such as graphlet degree signatures, and the presence of and the number of cliques, are used as measures of topological similarity. Topological information is preferred over sequence information (Davis *et al.*, 2015; Malod-Dognin and Pržulj, 2015). Most aligners of the GRAAL family, GRAAL, H-GRAAL, C-GRAAL and L-GRAAL are purely topological and identify statistically significant subnetworks or complexes based on only a few topological evaluation measures. These aligners have wider application as they can be applied to any type of networks, and are not limited to only biological networks. Some other topologically based aligners are NetCoffee, GHOST and MAGNA.

Existing aligners either produce promising results in identifying biologically or functionally significant alignments, or are effective in producing topological fit, but few achieve both well.

Pairwise Alignments

A pairwise PPI network alignment is an alignment limited to only two species, i.e., $k=2$. Given two networks, it finds an optimal matching of nodes between the two. The main objective of aligning two PPI networks from two species is to find conserved proteins in the two species (Park *et al.*, 2011; Tatusov *et al.*, 1997). Most published work on network alignment focuses on pairwise alignment. Given two or more PPI networks, one can perform two types of alignments: global alignment or local alignment.

In global alignment, each node of one network is aligned to one and only one node in the other, producing a single overall match of two or more networks. In global network alignment, each node in the smaller network is uniquely aligned to only one best matching node in the larger network. Such an alignment detects a maximal subnetwork, which is useful in functional orthology prediction.

In contrast, local alignment attempts to find the best alignment of subnetworks of one network with subnetworks of another, without worrying about how other nodes line up. Local alignment methods may produce one-to-many node alignments, where a node from one network may be aligned to more than one node from the other network. In local alignment, small regions of similarity are matched independently, and several such regions may overlap in conflicting ways. Computationally, local alignment is less expensive than global as global alignment aims to find a single large consistent match.

A simple example showing the difference between global vs local network alignments is illustrated in Fig. 1.

Global Aligners

In this section, we review state-of-the-art global network aligners. We categorize them into four types: IsoRank aligners, GRAAL family aligners, Index-based aligners, and other aligners that have no particular features in common. Most of the aligners surveyed work in two main stages. First, a similarity matrix is calculated to indicate the similarity of a node in one network to a node in the other network. The similarity matrix is computed based on various standards depending on the aligner. In the next step, the similarity matrix is provided as an input to a matching algorithm to extract an alignment. These matching algorithms are usually approximate to reduce their running time, with the *seed-and-extend* approach being particularly common.

IsoRank Aligners

The IsoRank algorithms (Singh *et al.*, 2008; Liao *et al.*, 2009), are the earliest developed global aligners. The basic IsoRank algorithm has two major versions. While the first version deals with global pairwise network alignment, the second version of IsoRank solves the problem of global multiple network alignment. The main idea of the IsoRank algorithm is to use an algorithm similar to Google's *PageRank* (Page *et al.*, 1999) to estimate node similarity, by recursively defining node similarity in terms of the similarity of a nodes' neighbors.

Fig. 1 Comparison of local and global network alignment. Dotted lines connecting nodes from different networks (of different colors) depicts an alignment of the node pair. (a) Local network alignment (one-to-many alignment); (b) Global network alignment (one-to-one alignment).

IsoRank

IsoRank (Singh *et al.*, 2008, 2007) tries to maximize the total number of nodes matched among the aligned networks. To accomplish this goal, a node from the first network is assumed similar to a node from the second network only if they both have similar neighborhoods in their respective networks. This intuition can be formalized as an eigenvalue problem for the aligned networks. It starts by calculating the scores R_{ij} , known as the quality of match, between nodes i and j ,

$$R_{ij} = \sum_{u \in N(i)} \sum_{v \in N(j)} \frac{1}{|N(u)||N(v)|} R_{uv} \quad (9)$$

where $N(x)$ represents the set of x 's neighbors. The R_{ij} scores are used to write an eigenvalue equation $R=AR$, where R is the vector of all R_{ij} s, A is a doubly-indexed $|V_1||V_2| \times |V_1||V_2|$ matrix defined as

$$A[i, j][u, v] = \frac{1}{|N(u)||N(v)|} \quad (10)$$

for $(i, j) \in E_1$ and $(u, v) \in E_2$ and 0 otherwise. It is remarkable that A and R are vast in terms of size, but both are sparse matrices and can, therefore, be efficiently computed by matrix calculation techniques such as the power method (Golub and Van Loan, 2012). This strategy is very similar to Leordeanu and Hebert's (Leordeanu and Hebert, 2005) spectral technique for correspondence problems, which was originally used for graph alignment in computer vision contexts.

To estimate biological similarity, IsoRank uses BLAST bit scores (Altschul *et al.*, 1990) to measure the similarity between any two proteins. Biological similarity can be combined with topological similarity and weighted using a parameter α . The eigenvalue equation can be adjusted to obtain this balance and is formulated as

$$R = \alpha AR + (1 - \alpha)E, \quad \alpha \in [0, 1] \quad (11)$$

where E is the normalized vector of sequence similarity scores. To assign more importance to topological similarity, α is set to a value close to 1.0. On the other hand, if α has a value close to 0.0, it indicates that topological similarity is not considered significant and sequence similarity is more important. In the original experiments in the paper in which IsoRank is introduced, the best value of α is determined to be 0.6.

Extracting the final alignment follows finding the node similarity matrix for IsoRank. The alignment can be obtained by solving the problem of maximum weight bipartite graph matching (Singh *et al.*, 2008), and many methods can solve it. IsoRank uses a greedy matching technique that first aligns the nodes with the highest similarity, and then matches the remaining nodes with the next-highest similarity, and so forth. This is a *half* approximation of the maximum weight matching problem (Preis, 1999).

IsoRank works in two stages. The first step is to compute the similarity matrix, and then the next step obtains the final alignment. *Gap* alignment is defined by IsoRank as a node that does not have a valid match in the network. Due to its significance as the earliest global aligner developed, nearly all subsequent aligners compare their results with those generated by IsoRank.

Improvements of IsoRank

Significant enhancements to IsoRank have been presented (Kollias *et al.*, 2012, 2013). *Network Similarity Decomposition* (NSD) (Kollias *et al.*, 2012) is one approach that makes a notable improvement by speeding up the calculation of the node similarity matrix R_{ij} . The principal concept in NSD is to uncouple the two input graphs, processing them independently, and to decompose the computation of R_{ij} itself. In addition to having better time complexity, this approach is also suitable to large-scale parallelization. According to the authors, extracting the alignment this way speeds up the process three fold in some cases.

Another augmentation that updates the second phase of IsoRank was introduced in Kollias *et al.* (2013). The same IsoRank methodology is implemented in two stages with different matching estimation algorithms. This implementation of IsoRank is roughly 30 times faster than the original algorithm. The same approach of calculating the similarity matrix and combining it with biological similarity, as in Eq. (11) is used in the opening phase. In the second step, two different bipartite matching heuristics are applied to improve the running time of the original algorithm. A matrix based matching algorithm called *half-approximation* (Preis, 1999), with linear time complexity, is pipelined with an auction-based algorithm (Bertsekas and Castanon, 1992) to find the best-weighted matching and obtain the final alignment faster.

IsoRankN

IsoRankN (Liao *et al.*, 2009) or *IsoRank-Nibble* is an enhancement to the original IsoRank, presented earlier. It solves the problem of global multiple network alignment and can be used as a global pairwise aligner when only two networks are given as input. IsoRankN also works in two stages as in the original IsoRank algorithm. In the initial step, a similarity matrix is calculated for each pair of input networks. This step can be accomplished by running the original IsoRank algorithm on each pair of networks without performing the second round of IsoRank, where the final alignment is produced. The final alignment is generated in the second phase of IsoRankN by using an iterative spectral clustering algorithm (Andersen *et al.*, 2006). The standard output format for IsoRankN and all global multiple alignment programs is two sets of nodes, one from each network, that are aligned to each other. This format makes it difficult to evaluate the alignments according to the evaluation metrics (Neyshabur *et al.*, 2013). We note that the original implementation of IsoRank can align at most 5 networks of various species, due to its exponential time complexity the time for aligning more than six networks with IsoRankN is extremely high and therefore impractical (Hu *et al.*, 2013). Moreover,

the iterative nature of IsoRankN and the need to update large matrices at each iteration makes IsoRankN, worthless in aligning large networks, particularly those that have more than 10,000 nodes (Shih and Parthasarathy, 2012).

GRAAL (Graph Alignment) Family

The GRAAL series is a collection of network aligners that use topological similarity, as estimated by graphlet degree signatures (Pržulj 2007), to align one network to another. The intuition behind this methodology is that the local topology around the proteins in their respective protein networks is exhibited in the different ways proteins interact. Hence, homology information is deemed to be encoded in the network topology in addition to sequence similarity (Kuchaiev et al., 2010). The GRAAL family consists of four different algorithms, namely GRAAL (Kuchaiev et al., 2010), H-GRAAL (Milenkovic et al., 2010), MI-GRAAL (Kuchaiev and Pržulj, 2011), C-GRAAL (Memisevic and Pržulj, 2012) and L-GRAAL (Malod-Dognin and Pržulj, 2015).

GRAAL

GRAAL (Kuchaiev et al., 2010) is acknowledged to be the first global network alignment algorithm that employs *only* topological similarity to align networks. Matching networks based on their topological similarity alone makes GRAAL suitable not only for biological systems but also for other networks, such as social networks.

The main concept that all GRAAL algorithms use is that of graphlet degree signatures. Graphlets are small induced subgraphs that are obtained from a larger network. The idea of graphlet degree is a generalization of a node degree, and it counts the number of graphlets a node reaches (Pržulj 2007). The graphlet degree signature is a vector describing the number of graphlets of each type a node touches. Graphlets consist of between 2 and 5 proteins and can be expressed as shown in Fig. 2 in terms of 30 different tiny graphs. A node can reach these graphlets in 73 different ways, based on the automorphism orbits of the graphlets in question. The main reason behind using graphlets up to size 5 is that network topology similarity of many real-world networks can be computed easily using these sizes. Furthermore, increasing the size of graphlets leads to an exponential rise in time complexity (Milenkovic et al., 2010).

For each node in the network, a vector that counts the frequencies of all the ways that a node reaches the 73 graphlets is built. When two nodes are aligned, the match depends on the similarity of their graphlet degree signatures. The distance between any two nodes is first estimated as a log-ratio, and its value is in $[0,1]$, where 0 denotes topologically identical nodes and 1 implies that

Fig. 2 Graphlets of up to size 5 nodes. Graphlets are induced sub-graphs that are extracted from a larger network. All possible graphlets that contain 2 to 5 nodes are labeled from G_0 to G_{29} . The figure shows all ways that a node touches a graphlet, shaded differently. These ways, known as *orbits* are labeled from 0 to 73. This figure is adapted from Pržulj, N., 2007. Biological network comparison using graphlet degree distribution. *Bioinformatics* 23 (2), e177–e183.

the two nodes are completely topologically different. If the signature similarity between any two nodes u and v is expressed as $S(u,v)$, and α is a parameter that balances the usage of node signature similarity, the cost, $C(u,v)$, of matching node u with node v can be presented formally as

$$C(u,v) = 2 - \left(\frac{(1-\alpha)(\deg(u) + \deg(v))}{\max d(G_1) + \max d(G_2)} + \alpha S(u,v) \right) \quad (12)$$

where $\deg(x)$ is the degree of node x and $\max d(G)$ is the maximum degree of any node in graph G .

After determining the cost of aligning all pairs of nodes, GRAAL employs a *seed-and-extend* matching algorithm to obtain the final alignment. It begins by aligning nodes that have the least cost and expands the alignment to the neighbors of these nodes within a specified scope, usually up to 4 neighbors in depth. Dense regions of the networks are prioritized to be matched first since this enables larger common subnetworks to be decided.

H-GRAAL

H-GRAAL (Milenkovic et al., 2010) (*Hungarian-algorithm-based GRAPh ALigner*) is the second pairwise global network aligner based on graphlet degree similarity. It can also be used to align any other type of network. The H-GRAAL matching phase uses the *Hungarian algorithm* (Korsah et al., 2007) to find a better topological alignment than the one obtained using GRAAL, at the cost of higher runtime. H-GRAAL uses the same methodology used in GRAAL, where graphlet degree signature distances between all nodes are computed and used with the same cost function Eq. (12). The only difference between GRAAL and H-GRAAL is the use of the *Hungarian algorithm* to find the minimum weight bipartite match instead of the greedy *seed-and-extend algorithm*. There is clear tradeoff between getting better results and the time required to get such an alignment. The time complexity of the Hungarian algorithm is $O(n^3)$. Applying such algorithm in large biological networks is expensive, even though the results are better than GRAAL, when graphlet degree signatures are used for computing similarity.

MI-GRAAL

MI-GRAAL (Kuchaiev and Pržulj, 2011) (*Matching-based Integrative GRAPh ALigner*) integrates several similarity metrics that can be used to align two nodes. These metrics are not limited to topological similarity, but can also include any biological similarity metric, for instance by allowing a similarity matrix (typically of BLAST bit scores). MI-GRAAL integrates *five* different metrics, four metrics for topological similarity and one metric for biological similarity. The topological metrics used are: (1) *graphlet degree signature distance*, (2) *degree difference*, (3) *clustering coefficient difference*, which measures the extent of a node's neighbors' connectivity to each other, and (4) *eccentricity difference*, the maximum graph distance between a node u and any node in the graph. The fifth metric and the only biological metric used in the implementation is the BLAST bit score (Altschul et al., 1990), which is used to measure sequence similarity between proteins.

The cost of aligning any two nodes is calculated separately for each metric in independent matrices. The five matrices are then combined into one *confidence matrix*, C , that contains, as a fraction, the confidence of aligning node u of the first network and node v of the second network, based on the scores from the five matrices. Ties are broken randomly. Contradictions can arise when two nodes should be matched according to one metric, but not according to the others. The greedy *seed-and-extend* algorithm is used to find the final alignment after constructing a node-pairs priority queue in decreasing order simultaneously with the calculation of the confidence score matrix. If nodes u and v are aligned, their neighbors are aligned using maximum weight bipartite matching. MI-GRAAL continues in this manner until there are no more nodes in the first network to be matched.

It is important to note that using the *seed-and-extend* approach in the MI-GRAAL methodology as a second step, to find the final alignment, instead of the Hungarian algorithm, actually enhances the quality of MI-GRAAL's alignments, despite the fact that the Hungarian algorithm finds optimal matches according to the given similarity matrix. This appears to be the case because the similarity matrix given is only an estimate. By using a *seed-and-extend* algorithm that is, itself, biased towards edge conservation, better alignments can be constructed in less time than H-GRAAL.

C-GRAAL

C-GRAAL (Memisevic and Pržulj, 2012) (*Common-neighbors-based GRAPh ALigner*) is another algorithm in the GRAAL series. C-GRAAL uses graphlet degree signatures along with another topological metric to heuristically maximize the total number of edges aligned in the two networks. C-GRAAL also optionally can take bit scores as input. Topology-based alignment makes C-GRAAL applicable to any type of network. In addition to using graphlet degree signatures, C-GRAAL also uses the presence of *similar neighborhoods* to inform its *seed-and-extend* heuristic. The idea behind using this property is that if any two nodes share the same set of common neighbors, these two nodes must be aligned along with their neighbors. This can be done by exploiting a node's *neighborhood density*, the sum of its node degree and all of its neighbors' degrees, denoted as $nd(v)$. Neighborhood density of each node in both networks is calculated and then the combined neighborhood density, $cnd(u,v)$, is used to measure the similarity of any two nodes,

$$cnd(u,v) = \frac{nd(u) + nd(v)}{\max_{u_i \in G_1} (nd(u_i)) + \max_{v_j \in G_2} (nd(v_j))} \quad (13)$$

where G_1 and G_2 are the two networks to be aligned. The neighborhood density is used to determine the starting nodes for the *seed-and-extend* stage. C-GRAAL starts with (1) aligning the pair with the maximum cnd , and (2) extends the alignment to the

neighborhood of this pair by aligning the two neighbors with the highest number of common neighbors. Step 2 is repeated until there are no nodes in the neighborhood to be aligned, before going back to the first step. After aligning all nodes sharing a common neighborhood, C-GRAAL greedily aligns any remaining unaligned nodes to get the final alignment, using a node similarity measure combining graphlet degree signature with BLAST bit score. Note, that if no measure of node similarity is used, C-GRAAL breaks ties randomly.

L-GRAAL

L-GRAAL (Malod-Dognin and Pržulj, 2015) (*Lagrangian Graphlet-based ALigner*) is the latest algorithm published in the GRAAL series. L-GRAAL integrates the topological similarity used in all of the GRAAL family, the graphlet degree signature, with a *seed-and-extend* strategy based on Lagrangian relaxation, which was introduced in NATALIE (El-Kebir *et al.*, 2011). A unique feature of L-GRAAL is the use of interactions in the mapped edges based on their graphlet degree signature. Regarding its performance, the L-GRAAL implementation takes into account only graphlets of size 2 to 4. According to the authors, the quality of the resulting alignment does not improve by considering graphlets of up to size five. L-GRAAL balances biological and topological similarities using the α parameter, as in Eq. (11).

We should note that there are two important points that make L-GRAAL different from the rest of the GRAAL family, where graphlets are employed, and NATALIE, where integer programming and Lagrangian relaxation are used. Mapped interactions are not considered in the rest of the GRAAL series. L-GRAAL differs from NATALIE in that NATALIE uses a naïve scoring function to map proteins while L-GRAAL maps proteins, based on their BLAST similarity score as follows:

$$\text{sim}(u, v) = \frac{\text{SeqSim}(u, v)}{\max_{i,j}(\text{SeqSim}(i, j))} \quad (14)$$

where u and v are nodes to be aligned, and *SeqSim* is the BLAST bit score (Altschul *et al.*, 1990). L-GRAAL compares favorably with many aligners. Topologically, L-GRAAL does better than most state-of-the-art aligners such as MI-GRAAL, MAGNA, SPINAL and NATALIE in finding the largest common connected subgraphs. When Edge Correctness (EC) is used, L-GRAAL is better than all the aligners to which it has been compared.

Index-Based Aligners

Most aligners have poor performance in terms of time complexity. Hours to days are the average running times for the majority of global network aligners. To speed up the process of extracting alignments, some use parallel processing, such as the NSD approach (See Section "IsoRank"). The other possible way to improve performance is to use indices. In this section, we review two aligners that are index-based.

IBNAL

IBNAL (Elmsallati *et al.*, 2016) uses a unique methodology to extract a global alignment. The main idea in IBNAL is to divide the PPI network into two different sub-sets of proteins. For each node in the subset of subordinate nodes, a vector is built showing the number of cliques that this subordinate node connects. All subordinate nodes and cliques are indexed and stored in advance to expedite the process of extracting alignment later.

In the step of extracting the alignment, a similarity matrix that measures the distance between every two subordinate node vectors is calculated. The similarity is computed as the Euclidean distance between two subordinate nodes, where a distance of zero means that these two subordinate nodes touch the same number of cliques, and therefore are likely to be a match. A priority queue is built for all pairs of subordinate nodes, and ordered based on their similarity scores. Pairs of subordinate nodes are then popped from the queue and aligned along with the cliques that they touch. Cliques of the same size are matched to each other. This process continues until the queue is empty. According to the published results, IBNAL shows high topological scores with the S^3 (Symmetric Substructure Score) metric and comparable results to other state-of-the-art aligners with respect to GOC (Gene Ontology Consistency). The performance of IBNAL is excellent compared to other aligners in terms of the time needed to align. It takes IBNAL only a few seconds to extract the final alignment.

SSAlign

SSAlign (Elmsallati *et al.*, 2017) is another global network pairwise aligner that takes advantage of indexes and functional annotations. The main idea in SSAlign is to index all maximal substructures of up to a specified size. Larger substructures are excluded from consideration, as the cost of extracting and indexing such substructures is very expensive in time. The maximum size of the substructures that SSAlign uses in its implementation is 5. Extracting and indexing all substructures is an offline operation. SSAlign starts by building a priority queue for each type of symmetric substructure based on the Gene Ontology Consistency (GOC) score. Substructures with higher similarity scores are popped first from the queue, and are likely to be matched. After building all queues, SSAlign starts the first step of matching by aligning symmetric substructures with the highest GOC scores. During this step, all substructures that are partially matched are placed in another queue for the next step. The second phase of aligning takes care of all substructures that were queued in the first step. All nodes that are not aligned in the partially aligned substructures are matched to their corresponding nodes. SSAlign finalizes the alignment by aligning all neighbors of each node in

the alignment set. SSAlign is compared to a set of state-of-the-art aligners. According to the authors, SSAlign has been the only aligner that obtains topological and biological scores at the same time with respect to GOC and S^3 respectively.

Swap-Based Aligners

PISwap (Chindelevitch *et al.*, 2013), MAGNA (Saraph and Milenkovic, 2014), and Optnetalign (Clark and Kalita, 2015) are examples of aligners that use a swap methodology to optimize the alignment. While the PISwap optimizes the BLAST bit score, Optnetalign can optimize multiple objectives. MAGNA is unique in that it can start with an alignment produced by another aligner and further optimize it.

PISwap

PISwap (Chindelevitch *et al.*, 2013) is a heuristic aligner that uses a swap-based approach to iteratively improve an alignment. PISwap begins by creating a maximum weight bipartite match between the two networks using the Hungarian algorithm, based on optimizing BLAST bit scores. Once this mapping has been completed, PISwap attempts to improve the alignment topologically by performing a local search using the 3-opt heuristic, interchanging the assignment of 3 nodes at a time. Only 3-opt moves that do not decrease the bit score matching of the alignment, but improve the number of matched edges, are allowed.

PISwap has been evaluated considering its ability to create new alignments, as well as to refine alignments created by existing aligners. PISwap's authors (Chindelevitch *et al.*, 2013) find that PISwap compares favorably with IsoRank, GRAAL, and PATH (Zaslavskiy *et al.*, 2009), when evaluated on the IsoBase data set. They also claim it to be more robust to noise than earlier methods.

MAGNA

MAGNA (Saraph and Milenkovic, 2014) is a recently-published genetic algorithm for performing pairwise global network alignment. While the published version of the algorithm optimizes topological fit, as measured by S^3 , updated versions have added the ability to optimize biological similarity as well, using the standard method of linearly combining topological and biological fit into a combined objective as in Eq. (11).

Genetic algorithms work by maintaining a population of candidate solutions. These solutions are ranked by their quality, and the best solutions are recombined (crossed over) with each other to produce new candidate solutions, which are then slightly perturbed (mutated) and added to the new population. The genetic algorithm technique has been applied to a huge variety of optimization problems with excellent results. MAGNA either begins with a population of randomly-generated alignments, or with alignments created by other aligners. It then scores these alignments by either their EC (Edge Conservation), ICS (Induced Conserved Substructure), or S^3 score, depending on the user's choice, and then crosses over the best alignments to create a new population. This process repeats until no further improvements in the population are found, or until a user-specified limit is reached. The crossover operation MAGNA uses is motivated by abstract algebra, and essentially finds an alignment that is "between" the two given alignments, where the only operation allowed to transform an alignment is to swap the assignment of two nodes. Interestingly, unlike most genetic algorithms, no mutation operator is used.

MAGNA is able to both improve alignments created by other aligners, as well as create high quality new alignments, as compared to IsoRank, MI-GRAAL, and GHOST (Patro and Kingsford, 2012). For a noisy yeast self-alignment problem, MAGNA is able to correctly align a higher number of nodes than these other aligners, even in the presence of significant noise. It is also able to find non-trivial overlaps in GO annotations between aligned pairs. MAGNA's running time is comparable to several other recent aligners, such as GHOST. A parallel version of MAGNA, named as MAGNA++ (Vijayan *et al.* (2015)) has also been proposed by the same authors with improved alignment quality and graphical support for the user.

Optnetalign

Optnetalign (Clark and Kalita, 2015) approaches the problem of optimizing multiple objectives differently from existing aligners. As a multiobjective memetic algorithm, Optnetalign is a generalization of a genetic algorithm that uses the concept of *Pareto dominance* to compare alignments in its population and decide which ones to improve. We say that alignment x Pareto dominates alignment y if x is strictly better than y , with respect to one objective, and no worse than y with respect to all other objectives. For example, if x has an S^3 of 0.3 and a GOC of 300, and y has an S^3 of 0.29 and a GOC of 300, we say that x Pareto dominates y because it has a higher S^3 while having the same GOC. Importantly, this definition of Pareto dominance implies that a set of alignments may all be non-dominated with respect to one another. For example, if x has an S^3 of 0.5 and a GOC of 200, and y has an S^3 of 0.3 and a GOC of 300, then x does not Pareto dominate y and y does not Pareto dominate x . Since there exists a tradeoff between optimizing topological and biological fit, Optnetalign attempts to find a wide variety of non-dominated alignments in one run of the algorithm, and can produce hundreds of alignments at once.

Optnetalign starts by creating a set of random alignments, and then iteratively improves them, maintaining a population of non-dominated alignments. This task is highly parallelizable, and each thread works by selecting a random existing member of the population and then attempting to improve it using swap-based crossover, mutation, and local search operations. Once a thread has finished performing these operations, it checks whether the new alignment is non-dominated in the population. If so, it inserts

the new alignment into the population, and removes from the population any alignments that are Pareto dominated by the new alignment. This algorithm is highly scalable, and can scale to many cores for improved performance. After a time limit is reached, Optnetalign outputs all the non-dominated alignments it has found.

Optnetalign was extensively compared to most of the alignment algorithms discussed above, and was able to find a much wider variety of alignments at a wide range of tradeoffs between topological and biological fit. Additionally, on many problems in the IsoBase data set, Optnetalign was able to find better solutions than other aligners. Because of the large number of alignments created in a single run, the authors suggest that Optnetalign's output can be used to evaluate the relationships between different alignment objectives, and potentially to experiment with new alignment objectives.

Other Aligners

In this section, we survey a set of aligners that use disparate methodologies to match PPI networks. Pure topological mapping, spectral properties of graphs, and a mixture of biological and topological fits are the main concepts that these algorithms use.

GHOST

Spectral graph theory provides many properties that can be used to improve the computational performance of programs dealing with graphs. GHOST (Patro and Kingsford, 2012) takes advantage of such properties to build a similarity metric that is used as a cost function to align the input networks. The spectral signatures of subgraphs of different sizes around a specific node are calculated using the normalized Laplacian, and combined with a greedy *seed-and-extend* algorithm to find the alignment. The name of this algorithm is inspired by the multiscale spectral signature, which is the topological metric used.

First, for each node, the spectrum of the induced subgraphs of the node, at distances up to 4 hops is computed. The spectra are calculated as a set of eigenvalues of the Laplacian matrix. Because spectra are not commensurate with graph size, these spectra are transformed into spectral densities, which condense spectral information into commensurable quantities. The distance between any two nodes' signature is calculated as a structural distance defined in Banerjee (2012). Biological similarity is integrated with topological similarity in GHOST using the same equation that IsoRank uses (see Eq. (11)).

The alignment is computed in two steps. The first phase finds an initial alignment, which is enhanced in the second step. The initial alignment is matched by exploiting the *seed-and-extend* methodology, matching the most similar pair of nodes, and then extending the alignment to the neighborhood of the matched pairs by approximating a solution to a quadratic assignment problem (Garey and Johnson, 1979). After aligning all neighborhoods of the selected pair, the seed-and-extend strategy chooses the pair that has the next highest score as the next seed and the algorithm continues in this manner until all nodes are aligned. Thereafter, the second phase tries to improve the initial alignment using a local optimization strategy similar to *PLSwap* (Chindelevitch et al., 2010), but with a slight difference in rules and evaluation. The enhancement improves the topological quality of the final alignment. All possible realignments for single nodes are given a score, and the one with a better matching score is used, thereby improving the alignment.

NATALIE

NATALIE 2.0 (El-Kebir et al., 2011) is a pairwise global network aligner that combines topological and biological similarity to create alignments by solving an integer linear programming problem. NATALIE allows a *gap* alignment if a node does not have a good match in the second network, sharing this feature with IsoRank (see Section "IsoRank"). NATALIE balances sequence similarity and topological similarity using the approach used in Eq. (11). NATALIE 2.0 also allows the user to configure a minimum sequence similarity threshold, below which two nodes will never be matched.

NATALIE 2.0 formulates the alignment problem as an integer linear programming problem, generalized from a quadratic assignment problem (Garey and Johnson, 1979). The solution to the quadratic assignment problem, can be extracted by combining a generalization of the dual descent method (Adams and Johnson, 1994) for the quadratic assignment problem with the sub-gradient method (Held and Karp, 1971) for optimization. NATALIE 2.0 is an enhanced version of the work presented in Klau (2009), which used the method of Lagrangian relaxation for optimizing the common maximum substructure. According to the results presented in El-Kebir et al. (2011), NATALIE 2.0 has a very fast running time compared to other aligners, especially IsoRank and GRAAL, which it has been compared.

NETAL

NETAL (Neyshabur et al., 2013) (*NETwork Aligner*) is a pairwise two-phase network aligner. NETAL uses both topological and biological similarity to build the similarity matrix as the first phase. Then, a greedy search method is used to construct the final global alignment of the two networks.

NETAL starts by iteratively constructing a topological similarity matrix based on the neighborhood of each node. Another similarity matrix, for biological scores, is constructed based on two conditions: (1) The two proteins matched have to be biologically similar, and (2) The neighbors of two matched nodes have to be biologically similar. The two similarity matrices are then combined and balanced using an α parameter similar to the one used in Eq. (11) (see Section "IsoRank"). After the similarity score matrix is constructed, the interaction score matrix is built to indicate an approximation of how many interactions will be conserved if a given pair of proteins are aligned. Finally, using the similarity score matrix and the interaction

score matrix, the final alignment is constructed using a greedy search method. The search method starts by aligning nodes that have the maximum similarity score and updating the interaction score matrix. This process continues until the two PPI networks are aligned. The implementation of NETAL is available as an online tool, but we note that the current online implementation supports *only* topological similarity. Even though NETAL's computations are similar to those of IsoRank, there is a significant improvement in time complexity. The matrices of topological and biological similarity are not changed once constructed. However, the computation of these matrices can be performed offline making NETAL's performance better than other aligners that it has been compared to, such as GRAAL and MI-GRAAL. NETAL shows good results with noisy networks, and it outperforms MI-GRAAL in dealing with such networks (see Section "MI-GRAAL"). While the current version of NETAL does not support biological similarity inputs, NETAL is an extremely fast aligner and produces alignments with high levels of topological fit (Clark and Kalita, 2014).

SPINAL

SPINAL (Aladağ and Erten, 2013) (*Scalable Protein Interaction Network ALignment*) is another global pairwise aligner available publicly as a tool. SPINAL was developed to overcome the lack of scalability of previous approaches, such as IsoRank and MI-GRAAL. SPINAL, like most aligners, first computes a similarity matrix, and then creates an alignment based on it. In the first *coarse-grained* phase, the similarity matrix P is calculated iteratively based on a set of contributors C and sequence similarity. The set of contributors is calculated by finding the maximum weight matching for the bipartite graph of neighbors of the pair of nodes being matched. The confidence matrix P is defined formally as

$$P(u_i, v_j) = \frac{\sum_{(a_i, b_j) \in C} \frac{P(a_i, b_j)}{\deg(a_i) \times \deg(b_j)}}{\sqrt{|C|}} \quad (15)$$

where C is the set of contributors and $\deg(x)$ is the degree of a node x . We should note that a_i is a protein belonging to the first network and b_j is a protein in the second network. The similarity matrix P is then integrated and balanced with biological information using an α parameter in the same way used in IsoRank (see Eq. (11)). In the second *fine-grained* phase, a greedy *seed-and-extend* approach is combined with local improvement and swaps to compute the final alignment from the confidence matrix P .

SPINAL, according to the authors, shows good results when compared with two other aligners, MI-GRAAL and IsoRank. SPINAL runs five times faster than MI-GRAAL, which is a significant improvement. It also finds more conserved interactions than MI-GRAAL and IsoRank. Later work, comparing more aligners, showed that SPINAL is also competitive with or outperforms several other aligners as well.

PINALOG

PINALOG (Phan and Sternberg, 2012) (*Protein Interaction Network Alignment*) is a global pairwise aligner that uses both topological and biological information to align PPI networks. Unlike most aligners, PINALOG works in a three-stage process that aligns the networks in successively more fine-grained steps.

PINALOG starts by identifying a set of *communities* in a step known as *community detection*. Communities are dense sub-networks extracted from the original PPI network. The idea behind extracting such communities is that these sub-networks usually represent functional groupings of proteins within one PPI network. These communities are matched in the second phase, based on their sequence similarity scores. The second phase is known as *community mapping*, and it is done in two sub-steps. The first sub-step determines the similarity scores of all extracted communities in both networks and represents them as a matrix. Then, this matrix is used to find the best possible matching of communities by optimizing the scores. We should note here that the similarity between any two proteins is formally defined as

$$\text{SeqSim}(u_i, v_j) = \frac{\text{BLAST}(u_i, v_j)}{\sqrt{\text{BLAST}(u_i, u_i) \times \text{BLAST}(v_j, v_j)}} \quad (16)$$

where $\text{BLAST}(u_i, v_j)$ is the BLAST bit score (Altschul et al., 1990) obtained by aligning the sequence of the two proteins u_i and v_j .

In the third phase, PINALOG extracts the final alignment by aligning the communities that have the best scores, and adding aligned communities until no more pairs can be added to the final alignment. The third phase of PINALOG is known as *extension mapping*, which matches the individual proteins within matched communities.

PINALOG has been compared against MI-GRAAL and IsoRank. PINALOG surpasses IsoRank when the LCCS measure is used. Even though the LCCS of alignments produced by MI-GRAAL is larger when compared with those produced by PINALOG, PINALOG alignments have denser structures and its alignments are better in terms of homology than MI-GRAAL (Phan and Sternberg, 2012).

PROPER

PROPER (PROtein-protein interaction network alignment based on PERcolation algorithm) (Kazemi et al., 2016), method uses the *percolation graph matching* (PGM) concept, which assumes that some extra information, apart from the input networks, is available in the form of a set of seed nodes or proteins from which the iterative procedure can initiate and incrementally extend outward to other proteins to detect conserved protein complexes. The PROPER algorithm takes BLAST bit scores as input, along

with the PPI networks. It works in two steps, firstly the BLAST bit-score similarities are used to find a set of node pairs that will be used as seeds for the PGM algorithm in the second step. The selection of the seed pairs is an important step. In the second step, the percolation graph matching algorithm is executed. The pairs of nodes with BLAST similarity scores above a threshold are selected in descending order of their scores, and are matched with the seed pairs to extend incrementally. Pairs that already have been matched are discarded. Several measures, such as edge correctness, node correctness, number of conserved interactions, symmetric substructure score, induced conserved-structure score, largest connected shared-component, gene-ontology consistency and average normalized bit score have been used to show the significance of the algorithm.

Local Aligners

We present, below, some well-known local alignment methods.

PathBLAST

PathBLAST (Kelley *et al.*, 2004) is a local protein-protein aligner, and is one of the earliest PPI alignment methods. Just as BLAST is used to align protein sequences, PathBLAST aligns protein networks. Interacting pathways, which are chains of proteins are aligned with a pathway from the second network, in which the proteins occur in the same order. In this way PathBLAST restricts itself to linear chains of interacting proteins, simplifying the problem of network protein alignment. The alignments in PathBLAST are scored based on the similarity of the protein sequences at each pathway position, the quality of the protein interactions. PathBLAST allows gaps in the other network pathway alignments, i.e., where interacting proteins in one path can be aligned with a path in the other network where the proteins are not directly connected but instead are connected by an intermediate protein, i.e., at a distance of two. A web-based tool for PathBLAST is available (see Relevant Websites section) for seven species, where protein ID or protein sequences are provided by the user. PathBLAST reports high scoring alignments of the query network and the network on one of the available species.

NetworkBLAST

NetworkBLAST (Kalaev *et al.*, 2008) is a local protein-protein interaction network aligner. Unlike PathBLAST which detects paths, NetworkBLAST detects complexes that are conserved through evolution, between two species. It can also find complexes in a single network or species. A web-based tool (see Relevant Websites section) is available for NetworkBLAST, which takes two PPI networks as input, and the BLAST E-value of pairs of proteins. In case of a single species, only the PPI network is required as input. NetworkBLAST predicts complexes based on the density of the subnetworks, using a log likelihood ratio score, and nodes with high scores in the subnetworks are identified and used as seeds in a greedy expansion procedure.

NetAligner

NetAligner (Pache *et al.*, 2012) is another local network aligner, which finds conserved interactions of proteins based on evolutionary distances. From two input PPI networks, NetAligner creates a complex protein network based on the proteins that are present in the networks, and the interactions from the interactomes of the species. Seeds are identified from the connected components detected from the initial alignment and then are extended to other seed vertices using gaps or mismatch edges. In this extended alignment graph, the connected components are the final alignment. NetAligner is available online (see Relevant Websites section), where the user can select from three categories: Complex to Interactome, Pathway to Interactome, or Interactome to Interactome. In the complex to interactome mode, the query is a complex which is mapped to an interactome of the same or a different species. In the pathway to interactome mode, the query is a pathway from a species, which is mapped to the interactome of a different or the same species. This helps detect pathways that are conserved across species. In the interactome to interactome mode, whole networks or interactomes are mapped to each other to find conserved complexes between the species.

MaWISh

MaWISh is an early PPI aligner (Koyutürk *et al.*, 2006). It is a local PPI aligner that predicts conserved complexes, which are defined as locally maximal heavy subgraphs. In an alignment graph, conserved complexes that have similar functions are highly connected and dense, with fewer interactions with other complexes. MaWISh uses a greedy approach, which finds conserved hub nodes and extends them to nodes which have edges in both networks. MaWISh uses the min-cut algorithm to find a minimum number of edges in which to partition the graph, maximizing the weight of internal nodes to extract subgraphs. In MaWISh, balance is not considered, and the weight of only a part of the graph is considered. This method iteratively produces new heavy subgraphs until the subgraph becomes redundant (when $r\%$ of nodes are present in subgraph). In this way locally maximal heavy subgraphs, corresponding to or conserved complexes, are extracted from the PPI networks.

Multiple Alignments

Optimally one PPI network to another is NP complete, and that is why all algorithms for 2-network mapping are heuristic. If we have k PPI networks (say $k=50$ through a few thousand), and are tasked with finding an alignment of all the networks, an already

Fig. 3 An example of multiple network alignments for N different PPI networks. Nodes are shown in varying shapes to represent diverseness among the protein molecules. Edges among the inter-network nodes indicate possible alignments with respect to certain alignment parameters such as ontology or topological similarity.

difficult problem becomes more difficult. Aligning multiple PPI networks may enable better understanding of protein functions and protein interactions, leading to better understanding of the evolution of species. Even though multiple network aligners have been designed and implemented to deal with more than two input networks, they can still be used as pairwise aligners when the number of PPI networks is only two. Graphically, we illustrate possible multiple alignments of diverse PPI networks in Fig 3. Below, we provide a brief sketch of some of the currently available multiple aligners.

Græmlin

Græmlin (Flannick *et al.*, 2008) stands for *General and Robust Alignment of Multiple Large Interaction Networks*. It is one of several algorithms that align multiple networks, and is unique in requiring phylogenetic information as input, in addition to network data. There are two versions of this algorithm. Whereas the first algorithm, known as Græmlin 1.0 (Flannick *et al.*, 2006), performs local alignment, the second version of Græmlin is a global aligner, known as Græmlin 2.0 (Flannick *et al.*, 2008). Græmlin is one of the earliest aligners and works in two phases. In the first phase, a feature-based pairwise scoring function is calculated as a vector of pairwise node and edge features. The node features take into account four evolutionary events, namely, (1) *Protein deletion*, (2) *Protein duplication*, (3) *Protein mutation*, differences in the sequences of two proteins from different species, and (4) *Paralog mutation*, differences in the sequences of two proteins from the same species. The edge feature is built based on two events (1) *Edge deletion*, loss of an interaction between two proteins from different species, and *Paralog edge deletion*, loss of an interaction between two proteins in the same species. Then, using a training dataset, Græmlin learns a scoring function that optimizes the vector of features. In the second phase, Græmlin updates the initial alignment results from the first step and continues to iteratively update the alignment till the final alignment is found. At each iteration, a node is processed according to four possible actions: (1) leaving the node, (2) creating a new class containing the processed node, (3) moving the processed node with another existing class, or (4) merging the current class of a processed node to another existing class. Iterations continue until the final result is obtained (Flannick *et al.*, 2008).

Græmlin is similar to other aligners in the number of phases required to get the final result. However, unlike most aligners, the inputs to Græmlin differ from those of other aligners. Græmlin takes as input the networks to be aligned and the phylogenetic tree relating the species under consideration. On the other hand, most aligners, pairwise or multiple, take as input *only* the networks to be aligned. Hence, most aligners developed after Græmlin do not compare their results with Græmlin, even though Græmlin works in linear time (Neyshabur *et al.*, 2013). Note that Græmlin learns its scoring function. However, it requires a set of true alignments among some species for this purpose. Hence the results produced by Græmlin depend also on the set of true alignments used to train its scoring function (Shih and Parthasarathy, 2012; Hu *et al.*, 2013).

SMETANA

SMETANA (Sahraeian and Yoon, 2013) is a global multiple network aligner. SMETANA stands for *Semi-Markov random walk scores Enhanced by consistency Transformation for Accurate Network Alignment*. The goal of SMETANA is to effectively find the maximum expected alignment for large networks. As with most aligners, SMETANA works also uses two phases. In the first phase, the similarity score matrix, which shows the likelihood of aligning two nodes, based in the semi-Markov random walk model estimated using the *semi-Markov random walk model* (Sahraeian and Yoon, 2012a). A similarity matrix is calculated for all pairs of networks to be aligned. The similarity matrices are then integrated and balanced with biological information using the α parameter as given in Eq. (11). Next, two probabilistic consistency transformations are used to improve the estimated probabilities of aligning the pairs of nodes that were calculated in the first step. The first transformation is called *Intra-network Probabilistic Consistency*, where each node's neighbor information is used to update the original scores. The intuition behind using such a consistency transformation is similar to that used in IsoRank (see Section "IsoRank"), where the probability of aligning any two nodes increases as the neighbors of these two nodes are aligned. The second transformation is known as *Cross-network Probabilistic Consistency*, where the information about other networks is integrated to enhance the alignment of nodes across all aligned networks.

The second phase of SMETANA finds the final alignment using the scoring matrices constructed and enhanced in the first phase. The greedy seed-and-extend method is used to iteratively construct the final alignment. Starting at nodes that have the highest probability, SMETANA adds nodes to the final alignment with two constraints: (1) The nodes of a pair (u,v) to be added are not already in the current alignment, and (2) The maximum number of nodes in either network is not reached.

SMETANA is one of the only algorithms that has been extensively compared to many other aligners. It has a faster running time compared to IsoRankN and Græmlin. SMETANA also shows good performance as the number of aligned networks increases. Unlike Græmlin, SMETANA does not require training datasets to learn its scoring function. When used as a global pairwise aligner, SMETANA also has running time comparable to MI-GRAAL and C-GRAAL (Sahraeian and Yoon, 2013). On the other hand, SMETANA does not perform well when used to align more than six large-scale networks (Hu et al., 2013).

NetCoffee

NetCoffee (Hu et al., 2013) is another recently published global multiple aligner. It is an aligner that can be easily adjusted to align any kind of networks, not only PPI networks. NetCoffee is also one of the few network aligners available as an online tool. NetCoffee is unique among aligners in that it is a four-phase aligner. Another important feature that makes NetCoffee unique is that it combines biological and topological similarities to match two or more PPI networks.

NetCoffee is the extension of a prior method, called *T-Coffee* (Notredame et al., 2000), which is used for multiple sequence alignment. For each pair of networks to be aligned, a set of all bipartite graphs is built, known as a *Bipartite Graph Library*. Then NetCoffee assigns weights to all edges using an integrated approach similar to *T-Coffee*. Sequence similarity is calculated as a log-ratio and integrated with topological similarity using the same α parameter method as in Eq. (11). The third step of NetCoffee is to build the search space by selecting all candidate edges from all bipartite graphs. The aim of this step is to reduce the time needed to produce the final alignment. As a final step, NetCoffee finds the final alignment from the candidate edges collected in the third step. The final alignment is defined as an optimization problem, which is solved by simulated annealing (SA) (Kirkpatrick et al., 1983). NetCoffee also allows the user to specify a bit score threshold, above which two proteins are forced to be paired.

NetCoffee has been tested comprehensively on three datasets and its results have been compared with IsoRankN, Græmlin and SMETANA. According to the authors' results, NetCoffee has the ability to deal with large datasets and produce a final alignment in a reasonable running time compared to the aligners mentioned above. NetCoffee is at least 2 times faster than the aligners it was compared with. As one of the most recent aligners published, NetCoffee provides a solution to running time limitations that other multiple aligners and it can work with large input networks.

Table 2 Comparison of different PPI Alignment techniques

Alignment	Technique	Year	Pairwise alignment	Multiple alignment	Topological approach	Functional approach

BEAMS

BEAMS (Alkan and Erten, 2013) (*Backbone Extraction And Merge Strategy*) is a global multiple network aligner. BEAMS combines both topological and biological similarity to calculate a global multiple alignment. Biological similarity between proteins is calculated based on BLAST bit scores and balanced with topological similarity using the α parameter in the same way as in Eq. (11). BEAMS starts by constructing a k -partite similarity graph, where k is the number of input networks. The constructed k -partite weighted graph works as a superset from which the final alignment is extracted. The final alignment is a subset, a *filtered version*, of the complete k -partite graph of the input networks, and contains only edges that have maximum weights. The step of constructing the similarity graph can be considered an off-line step, as it needs to be done only once in advance, and it does not affect the overall running time.

Like most of the surveyed aligners, BEAMS takes a two-phase approach. In the first step, known as *Backbone Extraction*, all possible k -cliques of orthologous proteins, *backbones*, are extracted from the similarity graph and the input PPI networks, in a greedy manner, where the maximum score k -cliques are extracted first. These backbones are clustered and merged to form the final alignment, in a step known as *Merge Strategy*. We should note that these two steps are heuristic; the goal is to maximize the score of the clustered proteins. The merging step uses the well known *seed-and-extend* strategy, where the *backbones* that have the maximum scores are seeded first.

BEAMS has been compared only against two other multiple aligners, SMETANA and IsoRankN. Using only one dataset, IsoBase (Park et al., 2011), BEAMS shows better results in terms of biological metrics. In general, the authors' results show that BEAMS and SMETANA produce very similar results, and these methods are mutually more different from IsoRankN.

A comparative summary of different aligners are given in Table 2.

Fig. 4 Comparison of different global PPI Alignment techniques based on GOC score.

Fig. 5 Comparison of different local PPI Alignment techniques based on GOC score.

Fig. 6 Comparison of different global PPI Alignment techniques based on Symmetric Substructure Score (S^3).

Table 3 Comparison of few multiple PPI alignment techniques

Methods	No. of conserved interactions (CI)	Total no. of interactions between clusters	CI/Total no. of interactions between clusters (%)	Alignment score (AS)
BEAMS	7,060	114,889	6.15%	0.5261
IsoRankN	5,978	109,364	5.47%	0.3970
SMETANA	13,498	122,450	11.02%	0.4766

Performance Comparison

A comparison of some of the global and local aligners based on Isobase database of *Caenorhabditis elegans*, *Mus musculus*, *Homo sapiens*, *Drosophila melanogaster* and *Saccharomyces cerevisiae*, is shown below. GOC scores produced by different global and local aligners are shown in **Figs. 4** and **5**. In terms of GOC, local aligner, AlignNemo and NetworkBLAST perform well compared to AlignMCL. **Fig. 6** shows the comparison of global aligners with respect to the topological merit function S^3 . However, due to the presence of many-to-many links in local alignments we could not calculate any S^3 scores for local alignments. From the results, it is clear that PINALOG is a good global aligner in terms of functional significance (**Fig 4**), whereas NETAL and MAGNA produces relatively better topological matches (**Fig 6**).

We also report a comparison between multiple aligners in **Table 3** which is reproduced from (Sahraeian and Yoon, 2013). For a detailed description of the comparison attributes, one can refer to (Sahraeian and Yoon, 2013). As seen in the results, BEAMS algorithm performs better in terms of conserved interactions (CI) as compared to IsoRankN, but SMETANA outperforms them (**Table 3**).

Conclusion

Comparative analysis of PPINs across different species using network alignment helps in discovering sub-network motif and pathways conserved during evolution. Aligning two PPI networks supplements sequence similarity with topological information so as to identify orthologs as accurately as possible. They also provide insight into the prediction of protein functions, phylogenetic tree construction and drug design. Both pairwise and multiple alignment methods are available for PPINs. Both local and global alignment methods have been proposed. Local aligners produce multiple small conserved regions of matches with many-to-many node alignment. On the other hand, global alignments look for a single large region with a one-to-one match. Local alignments are less computationally expensive than global alignments. We discussed different global and local alignment methods. Network topology, sequence and functional conservation scores are the most commonly used metrics for network alignment. Methods generally either score well in topological matching, or in functional matching but not in both.

Alignment of multiple PPI networks involves searching over extremely large spaces, and therefore the algorithms require efficient heuristics, but still produce high quality results. The challenges that need to be overcome are only starting to be addressed.

Introduction

Motivation

Biomedical research produces and needs to manage a large variety of information, leading to a diversity of computational challenges. Different high-throughput techniques produce the largest fraction of these data, contributing to improving our understanding of biological mechanisms in healthy and disease states. Hence the necessity for agile software solutions to adequately handle and analyze this information has become continuously more evident (Otasek *et al.*, 2012). Systems biology is a large part of computational biology that focuses on the comprehensive analysis of the relations between different biological factors, which leads to complex biomedical networks, such as protein-protein interactions (PPI), gene regulatory networks, or patient similarity networks. An important task within this framework is network visualization, analysis and interpretation, which is essential for interpretation and understanding of biomedical data. As data complexity increases with time, gaining insight from data becomes challenging without effective and scalable visualization methods. Individual network visualization tools differ greatly with respect to the supported features, scalability, and the analyses they enable. Further, it is important to consider the variety of potential users, who have a broad range of skills, expectations, and backgrounds, ranging from medicine and biology to computer science. Therefore, packages for network visualization must satisfy a diverse list of requirements (Agapito *et al.*, 2013):

- Fast and clear rendering of huge network structures and substructures;
- Interoperability with different databases that store biological network data, such as pathway or protein interaction databases;
- Integration of various standard annotation data sources, e.g., molecular function or localization from biological ontologies;
- Large range of functionalities and layouts, as well as feature expandability;
- User friendly querying and selecting of sub-networks (highlighting, zoom and focus);
- Compatibility with standard data input and output formats used for biological networks.

In this article, we provide a short introduction to various kinds of biological networks, their features and special visualization requirements, followed by a detailed description of the different layouts, their strengths and weaknesses, and discuss possible use cases. Furthermore, we elaborate how these networks can be annotated with additional information such as cellular location, function, or with “omics” data. Finally, the most commonly used software packages will be presented, their features compared, and their performance in terms of the defined requirements discussed, see [Table 1](#).

Biological Networks

The majority of biomedical networks incorporate data generated by various analytical technologies, such as metabolomics, transcriptomics or genomics. These “omics” data provide information about various states, molecules, or conditions across diverse biological mechanisms. Organisms’ phenotypes are the result of the combination of their genotype and the environment they live in. Research aimed at understanding any molecular mechanism underlying such phenotypes must take into account all available data, and not analyze single experiments and single condition data separately. Over the last several years, large proportions of the available data have been organized in public databases, which provide easy and centralized access via manual and automated queries. Modern tools dedicated to analyzing and visualizing biomedical networks can directly query these sources to answer specific research questions, integrate and annotate the retrieved data, and generate the corresponding visualizations and solutions needed to aid in data modeling and interpretation. [Fig. 1](#) gives an overview of such visualization and analytics workflow. In the following paragraphs we will briefly introduce the most common types of biomedical networks.

Epigenetic and Gene Regulatory Networks

Complex regulatory genetic and epigenetic systems mediate the expression of thousands of genes at any given developmental, adult, or disease stage of an individual (Davidson and Levin, 2005). The functional relationship between these particular genes, and their associated regulatory modules, define gene regulatory networks (GRN).

Gene Coexpression Networks

Coexpression networks are based on large scale experiments evaluating the concurrent transcription of coding or non-coding genome sequences, which can include microarray technologies as well as RNAseq data (Okamura *et al.*, 2014). Large-scale analysis

^aLatest version as available in August 2017.**Fig. 1** General overview of biological mechanisms and the corresponding types of omics data, which are subsequently stored in a number of network databases. The data can be utilized to create and visualize various types of biomedical networks that are finally, annotated with labels such as cellular location or function.

of coexpression networks based on similarity measures such as correlation, is a powerful tool to elucidate putative functional modules in the genome.

Protein-Protein Interaction Networks

Proteins perform the majority of cellular activities, including cell replication or growth, and are building blocks for most cellular structures. Many of these tasks are accomplished through stable and transient protein-protein interactions (PPIs). The entirety of all PPIs in a specific organism is commonly called the “interactome” (Cusick *et al.*, 2005). In order to computationally evaluate the interactome, it is typically represented as a graph or network.

Metabolic Networks

The entirety of all life-sustaining chemical transformations within a cell or microorganism is called metabolism (Hatzimanikatis *et al.*, 2004). Biochemical reactions are typically represented by edges connecting substrate and product metabolites, which are represented by product nodes, and create complex metabolic networks. The network structures further incorporate the different aspects of enzyme chemistry and structure. For instance, enzymes mediate, accelerate or decelerate metabolic processes and are a crucial element of the metabolic network.

Signaling Networks

Cellular signaling is the process of communication that mediates the basic activities and coordination of cells. The individual entities perceive and correctly respond to their immediate micro-environment. This cell communication is the basis of tissue growth, development, and repair, as well as the cellular immune response (Smith *et al.*, 2015). In a signaling network, intracellular or cell-surface receptors are activated by specific ligands, such as hormones or neurotransmitters, and the signal is carried through different cell compartments to reach the desired phenotype (Dinasarapu *et al.*, 2011).

Phylogenetic Networks

Phylogenetic trees are used to represent the processes and patterns of evolution. Visually representing the similarities among different phylogenetic trees supported by different genes is a powerful way for investigators to gain a better perspective on their evolutionary questions. In a phylogenetic network, edges represent evolutionary relationships between organisms (Wilgenbusch *et al.*, 2017).

Ecological Networks

Ecological systems can be represented by networks that comprise all interactions among the organisms within it (Ings *et al.*, 2009). The aim of ecological network analysis is to identify and understand the mechanisms on which the ecosystem is built, or that affect the ecosystem's stability. They can be subdivided into three broad types: food webs, mutualistic networks (including mutualistic interactions among plants and animals), and host-parasites networks. Visualizing the interactions and relations of different species enables a better understanding of the key principles and pillars of an ecosystem, and identifies crucial weak points.

Biological Networks Databases

A number of large-scale databases are available, providing easy and fast access to various network data. Prominent examples are BioCyc (Caspi *et al.*, 2014), KEGG (Kanehisa and Goto, 2000) and Reactome (Croft *et al.*, 2013) pathway databases for metabolic networks and signaling pathways, or BioGRID (Breitkreutz *et al.*, 2008), the IID (Kotlyar *et al.*, 2016), and STRING (Szklarczyk *et al.*, 2016) for PPI networks. For successful network analysis and visualization tools, it is useful to support either automated or easy manual data retrieval from these databases (see Section Network Visualization Software).

Layouts

An appropriate mathematical representation of a biomedical network is a graph. Biological objects such as proteins, genes, or species can be represented by nodes, while their interactions, for instance, biological reactions, gene regulation, or the genetic similarity of species represents the edges. This representation allows one to analyze the structural features of a network and reveals key components, for example, genes connected to certain cellular or disease mechanisms. It also allows one to apply a number of visualization techniques that enable the user to visually explore the data. The main goal of these techniques is to gain information by optimally presenting all objects and relations of the graph to the user (Agapito *et al.*, 2013). These so called layout algorithms, have been developed and used in mathematics and computer science for a long time. They aim to find an optimal set of coordinates for the nodes in the network in order to highlight underlying structures. To further improve network visualizations, both nodes and edges can be annotated with additional information, which can be highlighted by visual properties (e.g., color or shape), affecting the requirements and scalability of the layout algorithms. These additional visual features are described in Section Biological Network

Fig. 2 Network Layouts: (A) planar layout; (B) grid layout; (C) tree layout; (D) hierarchical layout; (E) circular layout; (F) hive plot; (G) heat map; (H) clustering layout. Networks created with the aid of NAViGaTOR 3.0 (Brown *et al.*, 2009). Available at: <http://ophid.utoronto.ca/navigator/>, exported in SVG, and finalized using Inkscape. Available at: <https://inkscape.org>.

Annotation about “Network Annotation.” Different criteria have been proposed, for example, to satisfy certain well-defined aesthetic principles, or other constraints, such as, flexibility, minimal node overlap, edge crossing, or the size of the drawing area. A brief description of the most common layout algorithms and their features is presented below and illustrated in Fig. 2.

Random Layout

The most simple, and often the initial, representation of a network is the random layout. The nodes and edges of a graph are arranged in a random way in the specified area. The main advantage of this technique is its simplicity and performance for both implementation and use. However, with increasing numbers of nodes and edges, the graph results in a “hair-ball,” which cannot be interpreted due to chaotic edge-crossings and node overlap. This type of layout is often applied to idealize architectures for dynamical models of genetic networks (Li and Kurata, 2005; Agapito *et al.*, 2013).

Planar Layout

Planar graph layouts are node centered and aim to reduce edge crossing by placing the nodes of the network along a straight line in the Euclidean plane, see Fig. 2(A). The main advantage is that individual nodes can be arranged with respect to any ordered node attribute, such as, node name, or biological features such as gene ontology and biological function. The edges are drawn as convex curves in one of the two half-planes separated by the line. A special instance of a line layout is the arc diagram, where each of the edges is drawn as a semicircle without crossing edges (Masuda *et al.*, 1990). The planar layout is simple and easy to visualize for small and sparse networks. However, for large graphs, screen space is not optimally used and an overview requires the use of a very small scale. Additionally, for highly connected networks, minimizing the number of edge crossings is very difficult. Frequently, planar layouts are combined into more complex layouts, for instance parallel lines or the hive layout, see Section Hive Plot Layout.

Grid Layout

The grid layout was developed with the aim of treating the network as a system of interacting particles, where the nodes are placed on a 2-dimensional, Cartesian grid (Li and Kurata, 2005), see Fig. 2(B). The nodes attract and repel each other according to a predefined energy function based on the network topological structure. Each specific configuration and corresponding layout, therefore, is rated by a certain cost based on this function. Similar to a molecular system, a low cost results in low energy levels and corresponds to a stable configuration. This layout is a systematic way of representing simple, locally connected but globally sparse, networks. A popular variation of the grid layout is the orthogonal layout, where edges are preferentially aligned with the grid and nodes are spread upon a larger grid, in order to minimize edge crossings, and to preserve local network topologies. Visualizing metabolic pathways according to conventional, grid ordered, textbook-like drawings is a difficult task for standard graph drawing techniques. These techniques mostly focus on a few linear or circular main structures or backbones and arrange other components relative to them (Li and Kurata, 2005). However, these techniques are generally not applicable to other networks, such as gene regulatory networks or signal transduction pathways, since it is difficult to find any mostly isolated paths to use as a backbone.

Tree Layout

This layout simply draws the nodes of the graph in a tree-like structure, often with a hierarchical organization, which creates clear and easy to understand graphs, see Fig. 2(C). It provides a natural way to visualize the global structure of a complex pathway (Di Battista *et al.*, 1994). A major advantage is that most implementations show a low complexity and are therefore scalable and highly efficient for visualizing large networks. However, problems occur when arranging a huge number of nodes in limited space. There are different types of tree layouts, including unrooted or rooted trees. The later is commonly drawn with straight or orthogonal polyline edges, while nodes are placed along horizontal lines according to their level. This type of layout is frequently applied to represent hierarchical structures like phylogenetic or family trees, and search trees. The T-REX web server, for instance, specializes in the analysis and visualization of phylogenetic trees and networks (see Relevant Website section) (Boc *et al.*, 2012). Nevertheless, this representation is generally not suited for non-tree structures that contain loops, such as those found in other biomedical networks, such as PPI or gene regulatory networks. In contrast, unrooted trees, also called free trees, do not have a specific root, and therefore do not follow a top to bottom hierarchy. Nodes are commonly arranged in concentric circles, according to their level, around the graph-theoretic center of the tree (Di Battista *et al.*, 1994).

Hierarchical Layout

In a hierarchical layout or layered drawing, nodes are constrained to lie on a set of equally spaced horizontal lines, called layers, with the goal of reducing the number of edge crossings (Di Battista *et al.*, 1994), see Fig. 2(D). This layout has efficient and scalable implementations and creates nice visualizations for sparse networks, even if the number of nodes is large (Agapito *et al.*, 2013). However, the minimization of the number of overlapping edges is an NP-complete problem, which prevents its application for larger graphs (> 1000 objects). It can be used effectively for applications that provide a hierarchical assignment for the nodes, such as signaling pathways, pharmacokinetic models or the food hierarchy of a food web in an ecosystem. The layout can also be used in directed networks, where it is customary to order the graph such that all edges flow in the same direction, e.g., from top to bottom, or from left to right.

Circular Layout

The nodes in the circular layout are placed equidistant from the graph center (Mäkinen, 1988), aiming to minimize overlapping nodes, see Fig. 2(E). Despite its simplicity, the technique is widely used to visualize biological networks such as protein complexes, drug-protein, miRNA-gene and phylogenetic networks (Agapito *et al.*, 2013). A popular variation of the circular layout is the circos plot, which is generally used to visualize genomic or transcriptomic information (Krzywinski *et al.*, 2009). While the genomic region, a chromosome, or a specific set of genes is drawn as a large circle, edges can depict the gene regulatory interactions between the loci of distal genes, for instance, in cancer (Sumazin *et al.*, 2011).

Hive Plot Layout

More recently, a novel layout called the hive plot has gained popularity. Similar to other approaches, its objective is to create rational, informative and reproducible layouts. The nodes are placed on multiple radially arranged straight lines originating in the center, representing linear axes with respect to a well-defined coordinate system, see Fig. 2(F). This creates a compact and reproducible layout with perceptual uniformity, where connections are easy to follow (Krzywinski *et al.*, 2011). A common application of hive plots is the comparison of transcript splicing ratios between individuals or genotypic groups (Wu *et al.*, 2013). While each of the linear axes corresponds to a splice junction, individual events are represented by curved edges that circle around the center, connecting all axes.

Fig. 3 Radial network layouts: (A) radial view; (B) balloon view. Networks created with the aid of NAViGaTOR 3.0 (Brown *et al.*, 2009). Available at: <http://ophid.utoronto.ca/navigator/>, exported in SVG, and finalized using Inkscape. Available at: <https://inkscape.org>.

Edge-Matrix Layout

Edge-matrix or heatmap visualizations of networks, can be utilized to depict the edges and edge weights between the vertices in a network. Directed networks result in a non-symmetric matrix. Weighed edges can be plotted via a range of colors, similar to the commonly used similarity matrix. This visualization can highlight densely connected subnetworks, by clustering the nodes according to a topological or content specific similarity (Gove *et al.*, 2011), see Section Graph Partitioning Algorithms for more details.

Cluster Layout

The aim of the cluster layout is to reduce the complexity of the network, by grouping similar nodes into a smaller number of visible representatives. This improves the clarity of the graph and simultaneously substantially increases the performance of layout rendering. In order to cluster the nodes, a similarity or distance metric is required, which can either be content or topology based. These could be, for instance, sequence similarity or based on topological cliques (see Section Graph Partitioning Algorithms) (Agapito *et al.*, 2013). A special variation of this layout, called a clustered circular layout, was developed as an informative technique to visualize PPI networks. The proteins can be clustered or annotated by their function, e.g., Gene Ontology (Fung *et al.*, 2010).

Radial Layout

The radial layout or balloon layout are special tree-based visualizations incorporating the idea of circular layouts (Herman *et al.*, 2000). The radial approach places the nodes onto concentric circles relative to their depth in the tree. Each subtree is subsequently plotted over a sector of the circle, while the algorithm guarantees that there is no overlap between adjacent sectors, see Fig. 3(A). The balloon view of a tree projects all sibling subtrees onto circles attached to the father node, see Fig. 3(B). An example for the radial network is presented by Djebbari *et al.*, where the center node. represents the biological complex ribonucleotide reductase. Proteins interacting with the components of a protein complex are connected via edges to a composite vertex, that represents the entire complex. Visualizations like this can show higher-levels of organization while maintaining the hierarchical structure of the biological complex (Djebbari *et al.*, 2011).

3D Layout

While analytical technologies moved from single experiments to high-throughput methods, biological networks started growing tremendously in the number of nodes as well as number of connections that they contain, creating the so called hairball effect. These huge numbers of nodes, densely connected with each other, result in various challenges for the performance of network analyses, but especially for visualization (Pavlopoulos *et al.*, 2015). A potential solution is to shift from two-dimensional (2D) to three-dimensional (3D) representations. A few software packages, such as Pajek, a previous version of Navigator, or the Cytoscape plugin 3DScape (Wang *et al.*, 2013), utilize the 3D space to show data in a virtual 3D universe.

Besides simply applying the same techniques in 3D, there are different ways to utilize the third dimension; for instance, by systematically implementing the concept of multiple layers for hierarchies as provided by Arena3D (Pavlopoulos *et al.*, 2008a).

In general, a 2D visualization provides the user with immediate visual feedback, while, in contrast, 3D rendering requires more interactivity between user and software with respect to the data but facilitates the potential discovery of relevant features that remain hidden in 2D. The relative advantages of 3D versus 2D visualization, depend on the task at hand, the data, and user skills; therefore, hardware acceleration and performance versus visual benefits have to be carefully considered when deciding between 2D and 3D visualizations (Pavlopoulos *et al.*, 2015).

Layout Algorithms

Automated network layouts, such as force-directed layouts, can be considered to be data-driven, unsupervised methods. They aim for a node organization based on network topology or connectivity, and are *de facto* multi-dimensionality reduction techniques (Baryshnikova, 2016).

Force-Based Algorithms

In general, force-based algorithms can be seen as a variant of multidimensional scaling (MDS) applied to graph-theoretic distances. It is a state-of-the-art group of algorithms that aims at estimating layouts for directed and undirected graphs on the basis of stress minimization. The elements of the graph are considered as objects with physical properties that are attracted and repelled by, e.g., electrical forces.

Spring embedded algorithms

Among the first force-directed approaches are the so called spring embedded algorithms, such as the Fruchterman & Reingold (Fruchterman and Reingold, 1991) and Eades algorithms (Agapito *et al.*, 2013). In these approaches, each node is represented as an electrically charged object, which is linked by springs representing an edge. In such a system, objects of equal charge repel each other and edges represent resistance, while two nodes attract each other when they have opposite charges. The system converges to an equilibrium of attracting and repelling forces by iteratively updating the positions of each node. These algorithms are particularly suited for weighted networks, where each edge is assigned a certain value representing, for instance, sequence similarity. The complexity of the algorithm is relative to the size (nodes and edges) of a graph, resulting in very time-consuming layout processes for large graphs. Due to their ability to effectively represent complex biomedical networks, force-directed layouts are implemented by the majority of network visualizations tools.

Kamada-Kawai algorithm

In contrast to the previous algorithm, this algorithm is more complex to encode, but often provides excellent results (Agapito *et al.*, 2013). Kamada-Kawai algorithm is based on the concept of graph theoretic distances between the objects (Kamada and Kawai, 1989). The distances between the different nodes can be determined by the lengths of shortest paths between each pair of nodes. These distances can be represented as spring forces that are directly proportional to the graph theoretic distances.

Graph drawing with intelligent placement

Graph dRrawing with Intelligent Placement – GRIP – has been designed to effectively visualize very large graphs (Gajer and Kobourov, 2002). It applies a multi-dimensional force-directed method in combination with a fast energy function minimization. A simple recursive coarsening scheme is employed, where vertices are placed intelligently, rather than randomly. Additionally, sets of nodes are placed simultaneously, at positions in close proximity to their optimal location. Therefore, the running time and space complexity of a network are near linear in the number of vertices.

Graph Partitioning Algorithms

While most layout algorithms try to optimize the general overview and aesthetics of a network, others such as graph partitioning algorithms, intend to infer topological meaning. Further, it is often advantageous to utilize such partitions for abstraction or complexity reduction, in order to reduce the visual complexity of the network (Herman *et al.*, 2000). Various partitioning algorithms are available and aim to identify local, topological or content based groupings. Methods that focus on structural information about the graph are often called structure-based partitioning methods; popular examples include community, motif, clique search, and structure-based clustering. Various software packages have been dedicated to solve these tasks, such as GraphCrunch (Kuchaiev *et al.*, 2011) or Mfinder (Milo *et al.*, 2002). In contrast, content-based approaches use semantic data associated with the graph elements to perform clustering. In a plane graph (see Fig. 4(A)), partitioning information can be utilized to visually indicate the groups within a network, by color or shape (see Fig. 4(B)), to reorganize the graph according to the grouping (see Fig. 4(C)), or to reduce the visual complexity of the network by replacing the elements of each group by a new representative object and applying mechanisms such as edge-bundling or node collapsing (see Fig. 4(D)). Decreasing the number of objects to be plotted improves both the clarity and performance of layout and rendering (Herman *et al.*, 2000). Furthermore, several tools enable stepwise moving up and down between different levels of detail as needed in order to evaluate biological meanings.

Probabilistic Graph Layout

The most recent combination of force-based and partitioning algorithms is called probabilistic graph layout, and aims to visualize uncertain networks using the underlying probability distributions of nodes and edges (Schulz *et al.*, 2017). Furthermore, the algorithm maps the probability distributions of edges to visually perceivable colored areas and shapes. Schulz *et al.* explored many aspects of filtering and depicting sets of overlapping partitions and points while maintaining the visibility of the underlying network topology, and thereby addressed various challenges raised by both force-based and partitioning approaches.

Fig. 4 Graph Partitioning Layout. A randomly generated graph visualized with the GRIP layout (A), application of community search by Navigator 3.0, and coloring by community (B), ordering according to communities each visualized using GRID (C), complexity reduction via merging community nodes and edges (D). Networks created in NAViGaTOR 3.0 (Brown *et al.*, 2009). Available at: <http://ophid.utoronto.ca/navigator/>, exported in SVG, and finalized using Inkscape. Available at: <https://inkscape.org>.

Biological Network Annotation

The visualization of large biological networks often results in an incomprehensible hairball, which is not directly interpretable. Although visual graph layouts hold great potential for uncovering hidden patterns within these networks (Baryshnikova, 2016), they are typically optimized to generate esthetically pleasing visualizations and rarely focus on systematic analysis. Therefore, it may be difficult to extract useful information with respect to biological meaning.

The integration of additional information about the biological entities represented in the network, for instance genes or proteins, may facilitate the organization and the analysis of the networks, and therefore clarify and highlight key attributes (Koh *et al.*, 2012), see Fig. 1. These node or edge annotations can be included in the original data, such as network files, or imported from biological databases. Incorporating this annotation information in the network visualization, by modifying the appearance of nodes and edges, can greatly increase the interpretability of the network, see Section Visualization of Annotation Visual Annotation for examples. In the next paragraphs, we will give an overview of examples of annotation resources that provide valuable information that can be used to gain further insight into the molecular mechanisms the network or a sub-network represents. One can categorize annotation information either according to type of data (quantitative vs. qualitative) or data context (disease relevance, tissue, or cellular localization for genes or proteins, as well as habitats for species networks). In the following section we will discuss the value of quantitative and qualitative annotation for biological networks and will give examples for both.

Qualitative Annotations

Biological networks can be annotated on different conceptual and functional levels. For instance, elements in gene regulatory networks or PPI networks can be associated with pathways, tissues, sub-cellular localizations or diseases. These qualitative annotations can be visualized through qualitative visual attributes, such as color, size, outline, and shape.

Widely used sets of annotations are available from public biomedical databases and ontologies, often initiated by international consortia, aiming to provide consistent descriptions of biomedical entities, such as proteins and other gene products (Koh *et al.*, 2012). An ontology formally names and defines the terms, properties, and relationships among the entities that exist in a particular domain. In the following subsections we will discuss some of the most relevant ontologies for the annotation of biological networks. Moreover, we will introduce a few of the most popular types of annotation. The majority of biomedical network research tackles the systematic analysis of genes, their products, their interactions, or their involvement in pathways; therefore, the focus of this section is set accordingly. Finally, we will also present relevant examples for other biological or medical networks.

Biological function

Various databases and ontologies provide information about the biological functions of proteins, for instance. The Gene Ontology (GO) initiative was created to provide consistent descriptions for large sets of gene products across databases, and has become a widely used source of information (Ashburner *et al.*, 2000). It provides three controlled and hierarchically organized vocabularies, “biological process,” “molecular function,” “cellular location,” each corresponding to an independent biological domain. The GO project aims to facilitate manual and automated access to information in the most effective (easy and efficient) way, and is therefore suitable for large scale annotation of PPI networks, and enrichment analysis (Smith *et al.*, 2007). It enables the identification of significantly over- or under-represented annotations in a given protein list or a PPI sub-network. The most commonly used ontology for this purpose is the biological process ontology. It is defined as a series of individual processes accomplished by one or more ordered assemblies of molecular functions (for instance, glycolysis or apoptosis). In contrast, the molecular function ontology encodes the specific role or roles a certain protein can possess and fulfill at a molecular level, for instance, catalytic activity or transmembrane transport. A more detailed description of GO definitions and policies can be found on the GO Web site (see Relevant Websites section).

Another essential ontological representation of protein-related entities is the PRotein Ontology (PRO) (Smith *et al.*, 2007). It formally describes taxon-specific and taxon-neutral protein entities of three major areas: evolutionary relationships of proteins, splice variants encoded by the same gene, and information on protein complexes.

In summary, modules of proteins that are part of the same process can be identified and can provide a functional interpretation of the network (Koh *et al.*, 2012). The same holds for proteins that are evolutionarily related or are part of the same protein complex. Changes in splicing variants, in contrast, can indicate a change in cell function, differentiation, or disease.

Subcellular localization

Proteins perform their functions in one or more cellular compartments. Compartmentalization is one mechanism of molecular regulation, as only proteins located in the same location can interact. As mentioned before, GO also provides an ontology for cellular components, indicating the primary location of a protein within the cell, for instance, the nucleus or mitochondrion. Using such annotations, visualization tools like Cell Where enable the user to depict proteins in a network according to their localization in a cell, as highlighted in Fig. 5.

Unfortunately, subcellular localization data are incomplete, redundant and often poorly structured, and a big part of the proteome has only computationally predicted localization (Veres *et al.*, 2015). Yet, it is fundamental to annotate PPIs with their subcellular localization, especially when analyzing molecular processes that span compartments.

Tissue annotation

When focusing on tissue-specific data, only the respective part of the whole data is going to be included in the network (Lopes *et al.*, 2011). The BRENDA Tissue Ontology (BTO) represents a comprehensive structured vocabulary of tissue terms for the source of an

Fig. 5 Location annotation of a set of genes. The figure was created in Cell Where (Zhu *et al.*, 2015), using standard parameters that create an example network. Cell Where is available at: cellwhere-myo.rhcloud.com.

enzyme. While focusing on enzymes, it comprises annotations for tissues, cell lines, cell types, and cell cultures from uni- and multi-cellular organisms (Gremse *et al.*, 2010). Another valuable resource is the TissueNet database, which annotates PPIs with information about tissue coexpression across more than 40 human tissues. The database associates experimentally-identified PPIs with human tissues if both genes have been shown to be co-expressed in the same tissue. This bridges the lack of information in interactomes, as many PPIs have no tissue-contexts (Basha *et al.*, 2017). Similarly, the PPI database IID, provides tissue information based on protein expression data and RNA sequencing as automated annotation when querying for interactions (Kotlyar *et al.*, 2016).

Studies have shown that tissue-specific networks evolve tremendously during growth and differentiation and, subsequently, functionally similar tissues tend to share a large number of PPIs. This highlights the necessity for properly annotated networks, especially when studying tissue-specific effects or developmental stages (Liu *et al.*, 2014).

Disease

Diseases interfere with an organism on many molecular levels. For instance, genetic or epigenetic modifications can lead to changes of gene expression, protein de-regulation, alternative post-translational modification, and a large set of consequences for survival (Zhong *et al.*, 2009). Many diseases are caused by or result in a sequence of these changes, altering PPI or metabolic networks. Therefore, prioritizing gene and protein prognostic markers, or identifying the most useful drug target candidates benefits from comparing PPI network differences between healthy and disease conditions.

The aim of the Human Disease Ontology (DO) is to establish an open source ontology to facilitate the connections between biomedical data that is relevant to human diseases (Kibbe *et al.*, 2014). The system incorporates various sources and types of biomedical data, such as, genetic data, clinical data, and symptoms, linked to human disease. Other ontologies focus on specific diseases or disease groups, for instance, Infectious diseases, Cardiovascular Disease Ontology (CVDO) or the Mental Disease Ontology (MFO). Other resources are provided by public databases focusing on human diseases and PPI networks, such as, HIPPIE or SPECTRA. HIPPIE provides context-annotated PPI networks incorporating information, such as gene expression, gene ontology (GO) and MeSH disease headings (Alanis-Lobato *et al.*, 2016). SPECTRA is an integrated database associating tissue and tumor-specific protein interactions in humans (Micale *et al.*, 2016).

Quantitative Annotations

In contrast to qualitative information, quantitative annotations rely on continuous measures, that are determined analytically, calculated, or estimated by different techniques. For PPI, experimental results might include differential gene expression, percentage of promoter methylation, number of post-translational modifications, mutation status, or protein expression and abundance. These are all measures that can be used and visualized in a network, as well as any numeric attribute of an entity - such as weight, size, or speed of a species in a species network, or disease specificity in a drug network that is of relevance to the particular research question. Many databases collect quantitative data that can be used to annotate nodes, e.g., GEO (see Relevant Websites section), (Edgar *et al.*, 2002)), ArrayExpress, (Kolesnikov *et al.*, 2014)), The Protein Atlas (Uhlén *et al.*, 2015)), while very few databases include data that can be used to annotate edges - one example being COEXPRESdb (Okamura *et al.*, 2014)). Quantitative measures can be visualized through quantitative visual attributes such as size (node type and outline), transparency, or shades of colors (Fortney *et al.*, 2010; Li *et al.*, 2016; Zhang *et al.*, 2017; Zeng *et al.*, 2016), for examples see Fig. 6.

Visualization of Annotation

Recent software tools for network visualization support a large variety ways to indicate the pre-430 viously described quantitative or qualitative annotations. Quantitative differences or categories of entities can be depicted as vertices of different color, shape, or highlights. In contrast, qualitative measures are often indicated by transparency, color scales, or node sizes. Similar strategies hold for edges, utilizing thickness, color and dashed lines. Fig. 6 depicts the most commonly used techniques for network annotations.

A – Colored categories, qualitative: This type of visualization is often used to indicate different categories, such as the ones obtained from biological process or molecular function Gene Ontologies. Another example is metabolic networks, that comprise elements that can have different roles, such as reaction mediator, substrates, or products, which can be visualized with different colors or shapes.

B – Node highlighting, qualitative: Nodes that have special meaning or indications, such as drug targets or network hubs can be emphasized by highlights.

C – Shaped categories, qualitative: Similar to color, different shapes can indicate different groups or communities. In gene-regulatory or PPI networks, frequently a combination of both is used, where green and red, and up- and down-pointing arrows indicate up- and down-regulated genes, respectively.

D – Node transparency, quantitative: This technique can be used for instance to put emphasis on nodes that show a high range in a quantitative measure, such as expression, statistical significance, centrality, etc.

E – Node size, quantitative: Similar to the previous, it can be used to represent the importance of vertices with respect to a continuous feature. Both transparency and size can significantly increase the interpretability of a network by fading out or reducing unimportant information.

Fig. 6 The annotation of biological networks using different visualization techniques. Networks created in NAViGaTOR 3.0 (Brown *et al.*, 2009). Available at: <http://ophid.utoronto.ca/navigator/>, exported in SVG, and finalized using Inkscape. Available at: <https://inkscape.org>.

Fig. 7 The visualization of network annotations using the spokes techniques. Networks created in NAViGaTOR 3.0 (Brown *et al.*, 2009). Available at: <http://ophid.utoronto.ca/navigator/>, exported in SVG, and merged using Inkscape. Available at: <https://inkscape.org>.

F – Edge transparency, quantitative: Transparency can be used to indicate the strength of an interaction. In gene-regulatory networks it can be utilized to visualize the probability that a regulatory factor controls a certain gene.

G – Edge colors, qualitative: Different colors can indicate different categories of network relations, for instance, in PPI networks, the difference between protein complexes and regular interaction, levels of positive/negative co-expression, or PPI deregulation in normal versus cancer tissues.

H – Edge thickness, quantitative: Similar to color and shade, the thickness of an edge can indicate different strength or type of relations. This can be beneficial to visualize, for instance, gene co-expression in a PPI or gene-regulatory network.

In addition to the previously described visual annotations, it is possible to add bar plots, so-called spokes, representing quantitative attributes, to each node. **Fig. 7** depicts two examples of the spokes visualization: (A) is a circular plot; similar in design to a circos plot, it shows two stacked levels of annotation attached to the outer side of each node, while the edges are centered in the middle. (B) represents a typical GRIP – layout tree; again each node is annotated by two different attributes in two opposite directions. In theory an arbitrary number of features can be stacked on top of or next to each other. This kind of visual annotation often presents the information in a much clearer manner, especially in combination with circular plots.

Network Data Formats

A major challenge for most network software tools is the complexity of biomedical input data and its many file formats (Pavlopoulos *et al.*, 2008b). Although, there is no common standard file format that is shared by all visualization tools (not even the selection presented in this article); all support the import of plain text files, but the structure requirements of each tool vary at least slightly. Until now, most of the current packages for biological network visualization provide their own input and output file formats to load and store the networks. Naturally, one would like to take advantage of complementary strengths of different tools; however, applying different algorithms and tools to the same dataset requires additional effort to reformat files according to each specific format and strongly limits feasibility. This is one of the of the crucial bottlenecks in exploring the variety of available network analysis and visualization techniques.

Nevertheless, a number of common file formats and standard languages for storing biological information have been introduced in order to increase incompatibility between different software packages. Many current open-source standards are XML-based languages, such as BioPAX, SBML and PSI-MI. They employ hierarchical structures, and therefore allow software or user-specified levels of complexity and specificity. In the following, we will briefly introduce the most widely used data formats for used biological networks.

SBML – The Systems Biology Markup Language is intended to describe qualitative and quantitative computational models in a declarative form that can be exchanged between different software packages (Hucka *et al.*, 2015). Since it was one of the first standards for biological network models, a large number of libraries and tools for editing, parsing, and converting SBML into other formats are available. Even though it was initiated as a language to describe biochemical reactions, SBML is now a widely accepted and supported format among biological network visualization tools (Pavlopoulos *et al.*, 2008b).

BioPax – This “pathway language” is a collaborative effort to create a standard format that allows the distribution, sharing, and exchange of information between pathway databases. Therefore, it is most suitable for the description of PPIs, genetic interactions, gene regulatory, metabolic, and signaling pathways (Demir *et al.*, 2010).

GML – The Graph Modeling Language, initially proposed by M. Himsolt in 1997, is a non-XML, text file-based format for storing network data, mainly focusing on portability, simple syntax, extensibility, and flexibility (Himsolt, 1997). Its simple structure consists of a hierarchical key-value list encoding for graphs that can be annotated with arbitrary information and data structures.

KGML – The KEGG PATHWAY database (Kanehisa and Goto, 2000), was created in 1995 and contains manually curated maps for metabolic and regulatory pathways (Wrzodek *et al.*, 2011). The KEGG Markup Language (KGML) was designed, to store these KEGG graph objects in order to enable automatic visualizations of KEGG pathways. It aims to facilitate computational analysis and modeling of PPI and metabolic networks, but the usefulness of this format is often limited by the mapping of gene names or single KEGG identifier. However, current software tools such as KEGGtranslator enable easy conversion to other data formats, such as SBML (Wrzodek *et al.*, 2011).

PSI-MI – Proteomics Standards Initiative – Molecular Interaction, abbreviated as PSI-MI, aims to support the exchange, comparison and verification of PPIs (Hermjakob *et al.*, 2004).

SIF – The Simple Interaction Format is the standard data format utilized by Cytoscape and is intended to allow graphs to be easily build from a list of interactions, simply specified by source node, type of interaction, and target node. This format makes operations on networks extremely simple, for example, merging networks is achieved by simply combining lists. However, SIF does not include any layout information, and forces the visualization tool to recompute it each time the network is loaded. herefore, it is not frequently used by tools that aim for high performance on large networks.

XGMML – The extensible Graph Markup and Modeling Language, is the XML equivalent of GML, and used for graph description (Punin and Krishnamoorthy, 2001). While GML is not related to XML, XGMML is specified so as to ensure a 1:1 relationship with GML for trivial conversion between the two formats.

SBML, BioPAX, GML, KGML, and PSI-MI are the languages most compatible among the described software packages for biological network data. A detailed overview of compatibility of tools and data formats is depicted in Fig. 8. Since BioPAX and XGMML support the richest hierarchy, and have the most general approach, they can span a broad range of biomedical network data including, for instance, genetic interactions, PPI networks, and small molecules interactions, as well as gulatory and metabolic pathways (Pavlopoulos *et al.*, 2008b). In contrast, experimental data such as molecular interactions and interaction networks are most efficiently handled by PSI-MI. SBML, is best suited for its intended purpose, the description of relationships and simulations.

Network Visualization Software

With the growth of omics data and approaches, a plethora of visualization tools have been created (see, for instance, OMICTOOLS, see Relevant Websites section). We compared the functionality and applicability of 15 freely available tools from the OMICTOOLS website that can be used without programming knowledge. They are listed in Table 1. Software tools have been tested on a 64-bit PC with 8 GB of RAM running Windows 7; web applications have been tested using Mozilla Firefox Version 55.0.2.

The volume of data that needs to be visualized and analyzed in systems biology can be daunting, as the integration of different datasets as well as different types of information can lead to networks including millions of nodes and edges – a size not many

Fig. 8 Comparison of compatibility of the discussed software packages and data formats.

tools can handle. Among the list of tools tested, only three of the 15 analyzed software packages, Cytoscape, NAViGaTOR and Pajek, were able to load a network of 120,000 edges. In particular, the basic version of Pajek is designed to visualize networks composed of up to 100 million nodes/edges, but there are two other versions (Pajek-XXL and Pajek-3XL) that can handle maximum network sizes of 2 billion and 10 billion elements, respectively, making it the most scalable tool (Pavlopoulos *et al.*, 2017). For other tools, a possible workaround is not showing the entire data set. For example, querying, filtering, or zooming into the network can help focus on a specific area or part of the network, reducing the rendering load and increasing the performance of the visualization tool. Navigation and zooming is quite common, but its drawback is the difficulty in relating the area that is currently visible to the overall context. Querying and filtering are better suited to see patterns spanning the entire network, in case part of the available information is not relevant to the analysis and can consequently be hidden. Most of the tested tools use at least one technique to focus on a smaller subset of the data, as shown in Fig. 9. Abstraction is an alternative and powerful approach, where irrelevant detailed information is removed but important general structures are maintained (Zoubarev, 2009). It is achieved by creating single representatives for groups of similar elements, i.e., a meta-node representing a set of nodes, a meta-edge representing a set of edges, and a meta-network representing a subnetwork. Only five tools, NAViGaTOR, Pajek, VisANT, esyN, and NaviCluster use abstraction to reduce network complexity.

Even when working with smaller networks – of the order of thousands of elements – the first and most important task of visualization tools is to dissect the data and highlight components that are more important, for instance, peripheral or central to the analysis being performed. To this aim, most visualization tools allow the user to (1) interactively change the network layout, (2) append quantitative and qualitative network annotations – sometimes allowing users to query directly fundamental biological databases – and (3) perform network analyses that can be mapped to the network visualization, and are necessary to emphasize biologically significant nodes or areas of a network.

As system biology networks are rarely small enough to be meaningfully visualized upon being uploaded in any visualization tool, layouts are the first and most direct step to unraveling the infamous hairballs. As described in Section Layouts, many layouts and layout algorithms have been suggested, but each visualization tool only provides a selected subset, as shown in Fig. 9. Random, hierarchical and circular are the layouts most frequently present, while all the tools use at least one type of force-based algorithm, varying between spring embedded, Kamada-Kawai, or GRIP. CellMaps and esyN are the two web applications with the most versatile layout tools, while Cytoscape, Medusa, NAViGaTOR, Pajek, VANTED and VisANT offer the best range of layouts for tackling the challenge of network visualization. Among these, NAViGaTOR is the only one (at the time of writing this article) that includes hive-plots, a more recent type of layout (Krzywinski *et al.*, 2011).

As discussed in Section Biological Network Annotation, a variety of data is available in system biology that can be used to annotate biological networks, and consequently visualized to achieve a more meaningful representation. Most public data used by researchers is available through open access databases, additionally users might intend to annotate their network with data derived from their own experiments. For this reason it is important that visualization tools offer both the possibility to query public databases as well as to import the researcher's own data. As shown in Fig. 9, almost all visualization tools allow users to upload their own network and annotation data, and a majority of the tools have the ability to query one or more publicly available databases. Importantly, once any type of annotation data is included in the network, the annotation needs to be visualized in the network, and in the following we will refer to visual annotation as the visual representation (color, shape, etc.) of the annotation

	Scalability			Import		Export		Annotation			Analysis				Layouts										Visual annotation

values. While most of the tools offer automatic mapping of annotations to the visualization, only half of the investigated tools enable the user to choose and manage visual annotations. Among the possible visual annotations, color is the most frequently available, while only 3 tools, Cytoscape, NAViGaTOR and CellMaps (also the three tools with most visual annotation features), offer the possibility of modifying transparency.

Network analyses add valuable information that is fundamental to meaningfully visualizing biological networks, especially those of larger size. Even if network analyses can be run separately using programs like R, Python, or dedicated tools such as GraphCrunch (Kuchaiev *et al.*, 2011) or Mfinder (Milo *et al.*, 2002), and then uploaded as annotation data, the possibility of running the analyses directly in the visualization software or web application makes the process more interactive. As highlighted in Fig. 9, most visualization tools support the application of topology or graph partitioning algorithms to the network. Furthermore, we evaluated which tools support the analysis of structural features. Shortest paths are supported by BiNA, Cytoscape, NAViGaTOR, VANESA, VisANT, esyN. Additionally, NAViGaTOR performs flow analysis and cliques search. Only three tools, Cytoscape, Pajek and Medusa, are able to perform analyses across multiple networks.

In our software evaluation, we further considered the possibilities of performing analyses using network annotation data – for example, pathway enrichment or co-expression analysis. NAViGaTOR, VisANT, VANTED, CellMaps, 3Omics, and NetGestalt support some of these analyses. Cytoscape does not perform data analysis in its basic version (the one we used for comparison in this section), but a collection of 326 plugins (at the time of writing) includes a module that enables direct control of network visualization and annotation through R, makes Cytoscape a very versatile software for network analysis in system biology (Saito *et al.*, 2012). Similarly, BiNA and Pajek provide an interface to R and its network analyses functionality. Note that, often, the proper usage of layouts, layout algorithms and visual annotations, have a larger influence on information gain than the selected visualization tool. Moreover, frequently, combinations and variations of layouts are needed to achieve optimal visualization in order to gain insights into biological networks and their mechanisms.

Fig. 10 visualizes a PPI network with different layouts. While no information can be gained from the grid layout visualization, the orthogonal layout shows the presence of different groups in the network and the visual annotation of nodes with large degree (Fig. 10C) enables the identification of key proteins. Fig. 11 visualizes a phylogeny with different layouts. The circular visualization hardly indicates the relations between the different taxa. The GRIP layout spreads the different branches of the phylogeny, such that different subgroups can be identified and further visually annotated.

The comparison across both standalone and web applications revealed a number of key features. Notably, more recent visualization tools are being developed as web applications rather than standalone programs. Web implementations have greater visibility and often provide a more intuitive user interface design that can make advanced visualization more accessible to non-expert users. Moreover, web-based applications are independent of the hardware being used. Stand-alone applications, on the other hand, have some software and hardware requirements that vary across tools, but they can work without an on-line

Fig. 10 Example of a PPI network, visualized in different layouts and annotations: (A) grid layout, (B) orthogonal layout, (C) node size annotation and (D) node color annotation. This figure was created by Cytoscape 3.6.0 (Shannon *et al.*, 2003) using the largest connected component of the sample yeast network provided by the tool Cytoscape. Available at: www.cytoscape.org/.

connection, do not rely on continuous support, in contrast to a web-server, and are more robust and scalable. Moreover, they ensure confidentiality, which is indispensable for delicate biomedical or clinical data.

Future Direction

Visualization is a powerful method to summarize and highlight key messages hidden in the huge amount of molecular data constantly being produced. In particular, supporting interactive visualization enables combining analysis with human insight – leading to “visual data mining.” While current tools are already more advanced and powerful than those of a decade ago, more interesting features and powerful developments are in sight for the next generation of tools. Handling of larger networks and more powerful analyses are possible with multiple threads running in parallel, including the use of multiple CPU cores and GPU-based computing that perform much faster than traditional single-CPU algorithms (Goddard *et al.*, 2017; Brown *et al.*, 2009). Even laboratories that lack proper computational facilities, the availability of cloud computing solves the problem of large network analyses. Faster rendering will be achieved with the development of improved graphic cards.

Simultaneously, a potential solution for the visualization of large scale networks is the transition from two-dimensional to three-dimensional representations. Over the last decade a number of software tools have developed modules that depict networks in a 3D universe, for instance, Pajek, a previous version of Navigator, Arena3D (Pavlopoulos *et al.*, 2008a), and the Cytoscape

Fig. 11 Example of a phylogeny, visualized in different layouts and annotations: (A) circular layout, (B) tree layout optimized by GRIP, (C) node size and color annotation. This figure was created by NAViGaTOR (Brown *et al.*, 2009). Available at: <http://ophid.utoronto.ca/navigator/>, exported in SVG, and merged in Inkscape. Available at: <https://inkscape.org>. The corresponding phylogeny was taken from Song *et al.* (2012).

plugin 3DScape (Wang *et al.*, 2013). However, the presentation of a three-dimensional graph on a regular two-dimensional screen, does enable better visual exploration, but does not exploit its full potential. In contrast, different visualization technologies – including virtual reality – could change completely the way we approach network visualization. For example, stereoscopy (in which separate images are projected to each eye, to mimic 3D stereoscopic vision) can be helpful for exploring large, complex networks, especially in combination with rotation or user motion cues; Similar comments apply to immersive visualization environments (where the user is “immersed” inside the image). While 3D and immersive technology has been available for some time, only recently implementations for biomedical network analysis, like iCAVE (Liluashvili *et al.*, 2017) or VANTED (Sommer and Schreiber, 2017), are starting to appear, and with the advent of more affordable virtual reality devices the future of network visualization looks very promising (and three dimensional).

At the present time, most of the visualization tools focus on single static networks, where knowledge collected from different conditions is gathered in a single graph (Blonder *et al.*, 2012). However, biological entities go through topological and dynamic changes, and many interactions exist only in a specific space or time. For example, specific interactions that occur in different tissues, at different times of the day, and at different stages of life, are topological changes to the network, where as propagation of a signal or spread of a disease are flow changes. Both types of dynamic changes can be captured with respect to time, for instance, following the distribution of shortest paths in a progressing sequence of networks can uncover potential molecular mechanisms hidden in the differences among such networks (Wong *et al.*, 2015). Future visualization tools will have to be able to capture, analyze and visualize these temporal network changes.

Closing Remarks

Although many network visualization tools are available today, we still face many challenges. The continuously increasing amounts of data in health sciences still pose a bottleneck for the visualization and manipulation of the resulting large-scale networks, which may comprise millions of nodes and edges (Pavlopoulos *et al.*, 2017). The computer science community has implemented a variety of efficient and effective algorithms and libraries for graph analysis and static visualization of large networks, from programing environments and libraries, such as R or Python, to more dedicated software packages and tools, such as, the Stanford Network Analysis Project (SNAP) and GraphViz. An important characteristic of this family of packages and tools is the ease with which we can combine and integrate various algorithms into new workflows and packages.

The development of flexible software tools with user-friendly and interactive graphical interfaces, that are able to handle large graphs, still remains a challenge when applied to biomedical research. The direct comparison of different network visualization tools shows that each has specific strengths and weaknesses, evolving from varying objectives and intended purposes. For instance, alternative network visualizations approaches such as Circos (Sumazin *et al.*, 2011) and hive plots (Krzywinski *et al.*, 2011) have been designed to solve the hairball effect that limits the understandability and interpretability of biological networks, but are very specific in their intended usage. Therefore, a good approach would combine the complementary advantages of different tools and algorithms.

However, in contrast to environments and libraries, like R and SNAP, the combination of the strengths provided by different visualization tools is strongly limited by the lack of compatibilities of data formats. Although a number of standardized formats for network data have been formalized, our experience showed that none have a general compatibility for a majority of tools. Even in the best cases, where import/export functionalities are implemented, node and edge attributes often cannot be transferred. A good future strategy for the community developing tools for biomedical networks would be to strongly facilitate the interchangeable usage of these tools by the broader support of standard file formats and accurate conversions between them, while simultaneously preserving a maximal amount of annotation and layout information.

Biographical Sketch

Anne-Christin Hauschild is a postdoctoral researcher supervised by Igor Jurisica at the Princes Margaret Cancer Center and University of Toronto. She finished her PhD in 2016 on Computational Methods for Breath Metabolomics in Clinical Diagnostics, which was funded by a Scholarship of the International Max-Planck Research School. She is involved in the Mapping Cancer Markers (MCM) project to systematically survey the landscape of potential gene signature patterns for multiple cancers, such as lung and ovarian. Her current research interests further include translational medicine particularly in arthritis, focusing on pre - versus - post surgical analysis of clinical as well as genetic data on a large number of osteoarthritis patients. During her scientific career she published 6 first and 10 co-author papers in international journals and was invited 7 times to give oral presentations at major bioinformatics conferences such as GCB, ECCB, GLBIO.

Chiara Pastrello is a research associate at University Health Network, Toronto. She is interested in cancer genetics and epigenetics, that she formalized in her medical genetics residency – focusing on the prediction of pathogenicity of unclassified variants in mismatch repair genes. She is further interested in cancer systems biology, specializing in network analysis, and the curation of expression data for multiple databases maintained at Prof. Jurisica lab. Her current research interests include the study of microRNAs in cancer signaling to distant metastasis, as well as the application of network analyses to study molecules and pathways playing a central role in cancer.

Andrea E.M. Rossos is a third-year undergraduate student in a Bachelor of Science program in Honours Biology at McMaster University. She was a Princess Margaret Summer Student who has worked in the Jurisica Lab for summer 2016 and summer 2017 as a recipient of the Ian Lawson Van Toch Internship Award

in Cancer Informatics. Andrea has been involved with data curation and development for projects such as microRNA Data Integration Portal (mirDIP), Cancer Data Integration Portal (CDIP) and Arthritis Data Integration Portal (ADIP). Andrea has also been involved with projects looking at the properties and diversity of biomolecule (miRNA, protein, etc.) databases. Andreas current research interests are the prognostic and diagnostic roles of microRNAs and other biomolecules in cancer and other diseases.

I. Jurisica is Tier I Canada Research Chair in Integrative Cancer Informatics, Senior Scientist at Princess Margaret Cancer Center, Professor at University of Toronto and Visiting Scientist at IBM CAS. He is also an Adjunct Professor at the School of Computing, Pathology and Molecular Medicine at Queen's University, Computer Science at York University, affiliate scientist at the Institute of Neuroimmunology, Slovak Academy of Sciences, and an Honorary Professor at Shanghai Jiao Tong University. Since 2015, he has also served as Chief Scientist at the Creative Destruction Lab, Rotman School of Management. He has published extensively on data mining, visualization and cancer informatics, including multiple papers in Science, Nature, Nature Medicine, Nature Methods, J Clinical Oncology, and has over 11,167 citations over the last 5 years. He has been included in Thomson Reuters 2016, 2015 & 2014 list of Highly Cited researchers, and The World's Most Influential Scientific Minds: 2015 & 2014 Reports.

Cluster Analysis of Biological Networks

Asuda Sharma, Hesham Ali, and Dario Ghersi, University of Nebraska at Omaha, Omaha, NE, United States

Introduction

Biological data is often represented as networks, as in the case of protein-protein interactions and metabolic pathways. Modeling, analyzing, and visualizing networks can help make sense of large volumes of data generated by high-throughput experiments. However, due to their size and complex structure, biological networks can be difficult to interpret without further processing. Cluster analysis is a widely used approach to extract meaningful information from biological networks, and works by grouping objects such that the similarity within a group is higher than the similarity between groups (Tan, 2006). Data clustering makes it easier to analyze and interpret the information contained in data (Xu and Wunsch, 2010). For example, clustering biological networks can help identify homologous proteins in different organisms or co-expressed genes.

Cluster analysis is based on two principles: (1) *homogeneity* (i.e., elements within the same cluster are similar to each other); and (2) *separation* (i.e., elements in different clusters are different from each other) (Jain et al., 1999). Clustering is often the first step in a data analytical pipeline, and is a well-known NP-hard problem. However, over the years a lot of heuristic algorithms have been developed which converge to a local optimum. Clustering algorithms are methods used to cluster the data into different groups based on a similarity measure, and as such they are not data-type specific. For example, a clustering algorithm that is used for clustering protein-protein interaction data can also be used to cluster social networking data. The selection of a clustering algorithm depends on the data characteristics along with the intended use of the results. It is a technique which must be run on a trial and error basis to find out the algorithm that best facilitates data interpretation. Data preprocessing and parameter optimization play a big role in the selection of a clustering algorithm.

Classification and *clustering* are often confused with each other but these terms have different working principles. Data classification (Fig. 1) is part of supervised learning where a collection of labeled data known as training data consisting of pairs of input cases and the desired outputs are used to construct a model for prediction of target output where the output values are unknown (Inza et al., 2010). In supervised learning, inputs are assumed to be the cause of outputs (Valpola, 2000).

In contrast, clustering (Fig. 2) is unsupervised learning and its goal is to partition the data samples into groups. Data labels are not available for unsupervised clustering (Inza et al., 2010). In unsupervised learning all the observations are assumed to be the result of latent variables (Valpola, 2000).

Some fields like community ecology use the terms classification and clustering interchangeably. However, in the field of life sciences, these two terms represent different concepts; classification of a biological network is different from clustering of a network.

Why So Many Clustering Algorithms?

There is no single definition of what a cluster is. Over the years, this has led to the development of many different clustering algorithms, creating a pressing need for objective benchmarks. Why are there so many different clustering algorithms and why is it

Fig. 1 Data classification.

Fig. 2 An example of clustering in two dimensions (https://en.wikipedia.org/wiki/Cluster_analysis#/media/File:Cluster-2.svg).

difficult to develop comparison benchmarks? The answer lies in the diversity of models and the induction principles underlying the different algorithms. Inductive principles are formal definitions of a cluster (Estivill-Castro, 2002). As the definition changes, the inductive principle changes, which in turn leads to new clustering algorithms. Further, for a single model and inductive principle, there are many algorithms that can be used to generate the optimized results. The differences in inductive principles are often the results of assumptions made by the researchers and the specific problem at hand. Given any data set, the first step is a hypothesis on how to group the data. This hypothesis leads to the development of a model which is then used for clustering the instances of data which are not seen. The mathematical formulation of the inductive principles is used to discriminate different hypotheses. It is also known as the clustering criterion. Therefore, models are the structures used to represent different clusters and the inductive principle is used to select the model that best fits a given dataset (Estivill-Castro, 2002).

Various clustering algorithms such as K-means, affinity propagation, spectral clustering, and hierarchical clustering have been developed to cluster different types of data generated from different sources. For the same data set, different clustering methods will generally give different results. There is no one single tool which can give the best clusters for a given data set. Clustering methods were at first divided into two main groups: hierarchical and partitioning methods (Fraley and Raftery, 1998).

Drawbacks of Traditional Clustering Algorithms

High throughput technologies along with advancements in computational prediction tools have resulted in many large-scale biological networks. Traditional clustering algorithms such as hierarchical, centroid-based, and density-based methods work well on biological networks of moderate size data, but these algorithms in some cases take too long to produce the clusters or fail altogether. This is particularly prevalent when the input network size is very large, such as functional networks for higher organisms (Jiang and Singh, 2010). In recent years, with the notion of biological networks already established, the trend has shifted from simply constructing biological networks to analyzing existing networks and finding out how the objects in the networks interact with each other. Clustering is the most common approach for network analysis and is used by many researchers to study functional modules and protein complexes and their functions.

The main problem with traditional clustering algorithms is that they were developed long before the recent advances in bioinformatics and they are for the most part domain agnostic. Hence, in many cases, they get confounded by some of the characteristics specifically associated with biological data. For example, in the K-means clustering approach, which is one of the oldest and most widely-used methods for data clustering, it is required to identify the number of clusters “K” in advance, which is not always desirable in dealing with biological networks. Another common clustering approach is hierarchical clustering which does not leave any data element (such as gene or protein) unclustered, which is an unnecessary restriction in the case of biological networks. Also, the outcome of almost all traditional clustering methods are strongly driven by a rather small number of features in the input elements, which is again not the case in dealing with biological data with many attributes (Huttenhower *et al.*, 2007).

Many clustering algorithms, especially graph-based and biclustering algorithms have been developed to overcome the limitations of traditional methods. Some of these algorithms, such as SAMBA, CLICK, and spectral clustering are developed primarily to deal with biological data. The next section describes the traditional and the newly-developed clustering approaches, highlighting some of the most widely used clustering methods for each category.

Types of Clustering Methods

The majority of the existing clustering algorithms can be classified into six categories based on the working principle of each cluster model.

Fig. 3 Traditional representation of hierarchical clustering.

Connectivity-Based Clustering

More commonly known as hierarchical clustering, connectivity-based clustering is based on the idea that nearby objects are more closely related than objects that are farther away from each other. Hierarchical clustering comprises several algorithms that form clusters by connecting objects based on their distance from each other. Different clusters are formed in a nested (or hierarchical) fashion at different distances, and the clusters are visualized as a dendrogram. These algorithms build a hierarchy of clusters which merge with each other at different distance levels (Fig. 3).

Along with a suitable distance measure between data points, the user must select a linkage criterion to define the distance between sets of data points. Some examples of linkage criteria include Unweighted Pair Group Method with Arithmetic Mean (UPGMA), single-linkage (which uses the minimum distance between objects), and complete-linkage (which uses the maximum distance between objects).

Hierarchical clustering algorithms may either operate in an agglomerative or divisive fashion. Agglomerative clustering involves grouping single elements into clusters, whereas divisive clustering involves dividing a dataset into different partitions or groups (Zhong, 2013). Hierarchical clustering algorithms do not return “ready-to-use” clusters. Instead, the user must cut the dendrogram at a chosen distance threshold in order to obtain non-overlapping clusters.

Centroid-Based Clustering

Clusters in centroid-based algorithms are based on the concept of a central vector, which may or may not be part of the dataset. These algorithms are also based on the distance between objects. Centroid-based clustering optimizations are computationally intensive; therefore, most centroid-based algorithms return approximate solutions, generated by local optimization. The most famous example of this class of algorithms is *k-means* (Fig. 4). It is one of the most widely used iterative algorithms and its appeal is ease of implementation and good convergence speed. The *k-means* algorithm seeks to minimize the squared distances between objects within a cluster, in an iterative manner. One drawback of *k-means* algorithm is that the number of clusters must be specified in advance by the user.

The general principle behind the *k-means* algorithm can be summarized by the following steps (Charrad *et al.*, 2014):

1. Select ‘*k*’ (number of desired clusters), then randomly assign *k* data points as cluster centers.
2. Temporary clusters are created by associating each observation with the nearest center.
3. New cluster centers are formed by calculating the gravity centers of the temporary clusters formed in step 2.
4. The observations are then reallocated to the clusters with the closest centers.
5. The procedure is iterated until the algorithm converges.

Distribution-Based Clustering

Distribution-based clustering methods are based on probability distribution models. Clusters are defined based on ‘same distribution’. The advantage of this type of algorithms is that objects are randomly sampled from a distribution. These methods are the perfect clustering approaches in theory but they suffer from overfitting, where a noise or error is modeled rather than the true relationship. The problem of overfitting can be corrected by using constraints, adding to the model complexity.

Gaussian mixture models that use the Expectation-maximization (EM) algorithm (Fig. 5) are one of the most widely used distribution-based clustering methods. A fixed number of randomly initialized Gaussian distributions are used to model the

Fig. 4 An example of k-means clustering (https://en.wikipedia.org/wiki/Cluster_analysis#/media/File:Cluster-2.svg).

Fig. 5 The EM technique.

dataset. The goal of the EM algorithm is to estimate the mean and the standard deviation of the clusters and to maximize the likelihood of the distribution of the data (Fraley and Raftery, 1998).

Two steps are performed iteratively until the model converges to calculate the maximum likelihood, even in the presence of missing data (Fraley and Raftery, 1998):

- i) E-Step (Expectation step): The value of each of the missing variables is calculated using the existing data, the current estimates and the current hypothesis. The old values are then replaced with these new values.
- ii) M-Step (Maximization step): The new values calculated in the E-Step are assumed to be the correct values. Maximum-likelihood hypothesis is calculated based on these new values and the old hypothesis is replaced with this new hypothesis.

The two steps are performed repeatedly until the model converges and each observation belongs to a certain cluster with a definite probability.

Density-Based Clustering

The assumption for these types of methods is that each point specific to a cluster belongs to a probability distribution (Banfield and Raftery, 1993). The main goal of the density-based models is the identification of clusters along with the distribution parameters. The clusters are recognized because of their high density as compared to the points outside the cluster (Ester, Kriegel *et al.*, 1996). Objects lying in the 'noisy areas' have lower density as compared to the cluster density. DBSCAN or Density-based spatial clustering of applications with noise is the most commonly used density-based clustering algorithm. It is based on the

Fig. 6 Density-based spatial clustering of applications with noise (DBSCAN).

“density-reachability” and “density connectivity” cluster model. DBSCAN shares the same principle as linkage based clustering; points are connected to each other based on certain distance threshold values. The difference between linkage and density clustering is that the density clustering algorithm connects only those points that satisfy a given ‘density criterion’ within a certain radius. For example, point “p” is density-reachable from point “q” if p is in the epsilon (ϵ) neighborhood of q and q is a core point. Points “p” and “q” are density connected if point “r” exists in such a way that both p and q are within the epsilon distance along with a number of points in its neighborhood. DBSCAN has low complexity as compared to other clustering algorithms (Moreira *et al.*, 2005).

Algorithm (Fig. 6):

1. A point p is selected.
2. For each core-point p create an edge to every point that is density-reachable from p in the ϵ -neighborhood of p .
3. All points are assigned to a cluster.
4. If p is a border point no points are density-reachable and DBSCAN visits the next point.
5. The process is continued until all the points have been processed.

Subspace Clustering (Biclustering)

Clustering algorithms can help in extracting group of genes with similar variations in expression level under given experimental conditions. Clustering has been identified as one of the most common approaches used for analyzing gene expression data and has been successful in identifying gene pathways and predicting gene function in several studies (Liu *et al.*, 2010). However, clustering algorithms have a major drawback when it comes to gene expression data, as gene expression may have different patterns in different sets of samples (Pontes *et al.*, 2015). To better characterize gene expression, clustering should be performed simultaneously on both dimensions: genes and samples. Another problem is that genes are often involved in different biological processes and as such they cannot be clustered in just one group (Gasch and Eisen, 2002). These drawbacks of the clustering methods are solved by biclustering methods, which have been successfully employed to study gene expression data.

Biclustering, also known as co-clustering, is a data mining technique that can allow the simultaneous clustering of columns and rows of a matrix. J.A. Hartigan introduced biclustering in 1972 (Hartigan, 1972), but the algorithm was generalized by Y. Cheng and G.M. Church in 2000, when they proposed a biclustering algorithm for biological gene expression data that was based on data variance (Cheng and Church, 2000). Biclustering has become a very important technique to study gene expression data and has helped in understanding functionally related gene sets under different conditions (Pontes *et al.*, 2015).

A bicluster is defined as a subset of genes that exhibit consistent patterns over a given subset of conditions (Tanay *et al.*, 2002). Given a gene expression matrix, the biological phenomenon it embodies can be characterized by a collection of biclusters, where each bicluster represents different gene behavior based on the experimental condition. Biclusters have no constraints on them; this often leads to the problem of overfitting. The algorithm is accompanied by a heuristic scoring method or a statistical model that define the significant biological behavior, to guarantee that the biclusters are meaningful (Tanay *et al.*, 2002).

Several biclustering algorithms have been developed to find significant biclusters in an expression matrix. Most of these algorithms use a cost function that helps determine the quality of biclusters (Pontes *et al.*, 2015). Statistical-Algorithmic Method for Bicluster Analysis (SAMBA) is one of the most widely used biclustering methods based on graph theory (Tanay *et al.*, 2002). SAMBA works in three phases:

Phase I

- 1) Modeling of the input gene expression data as a bipartite graph where the two sides of the graph nodes correspond to genes and conditions and the edges represent the significant changes in the expression.
- 2) Weights to the vertex pairs are assigned according to a probabilistic method and the genes (upregulated or downregulated) are considered in a condition if the standardization levels are above 1 or below -1 .
- 3) The choice of signed or unsigned graphs depends on the data.

Phase II

- 1) Hashing technique is applied to find out the heaviest bidiques in the graph; the algorithm looks for the 'k' best bidiques that intersects every gene or set condition.

Phase III

- 1) A local improvement procedure on the biclusters in each of the heaps is performed by the algorithm, then the best modification is applied to the biclusters until no score improvement is possible.
- 2) To avoid similar biclusters with only a slight difference in vertex sets, the algorithm greedily filters the biclusters whose intersection with a solution is above a set L%.

Graph-Based Clustering

Graph-based clustering is a collection of clustering algorithms that are based on various concepts of graph theory. In a graph, the objects are represented by nodes and the nodes are connected by edges which are assigned a weight, defined as the distance between two nodes. In graph clustering, nodes are grouped into different clusters by considering the weights on the edges of the graph and their weights, if weighted graphs are used to model the network. The clusters are formed based on homogeneity and separation such that clusters have high degree of edge density (or have edges of high weights in the case of weighted graphs) while few edges exist between clusters (or number of edges within each cluster is more than the number of edges between different clusters). Graphs can have weighted and unweighted edges depending on the data. Graph-based algorithms are widely used for clustering biological networks (Fig. 7). The past two decades have seen an increase in research of the continuity clustering algorithms as opposed to the classical methods such as k-means and hierarchical clustering (Schaeffer, 2007).

Markov Clustering (MCL), Spectral Clustering (continuity clustering algorithm) and Speed and Performance In Clustering (SPICi) are some of the most widely-used algorithms that were specifically designed to cluster protein-protein interaction networks, gene-expression data, and other biological data.

MCL

Markov cluster algorithms are based on the concept of random walks, which are calculated using Markov chains. Markov chains are a sequence of variables where the present state of the variable is independent of the past or future state (Van Dongen, 2000).

Fig. 7 Schematic representation of a graph network.

The algorithm simulates random walks and identifies densely connected areas within a graph. MCL algorithm is based on flow simulation within a graph; the flow is promoted where the current is strong and it is demoted where the current is weak. This process of flow simulations is made possible by transforming the graph into a Markov graph: a graph where the sum of weights of all the nodes arcs to one. The Markov process is used to compute the powers of the associated Markov matrix (flow expansion).

MCL is performed by alternating an expansion step, which allows simulated walks of long distance, with an inflation step that sharpens the structure of the local clusters. Expansion and inflation are operators that convert one stochastic matrix (elements of the matrix correspond to the probability values) into another. Expansion is a part of linear algebra and takes the power of a stochastic matrix by using normal matrix multiplication. Inflation, on the other hand, is a highly non-linear operator that takes the Hadamard power (powers are taken entry-wise) of the matrix and is followed by a scaling step such that the output is again a stochastic matrix (Lin *et al.*, 2007). The number of clusters is strongly influenced by the value of the inflation parameter.

Algorithm:

1. Input: An undirected graph, with power parameter 'e' and inflation parameter 'r'.
2. Creation of the associated matrix.
3. Normalization of the matrix.
4. Expansion by taking the 'e'th power of the matrix.
5. Inflation by taking the inflation of the resulting matrix with parameter 'r'.
6. Repeat steps 4-5 until a steady state is reached.
7. Analysis and interpretation of the resulting matrix to discover the clusters.

Bootstrapping is an important asset of MCL algorithm. It helps in retrieving cluster structures by using the imprint on the flow process. Some of the benefits of the MCL algorithm are: (1) it is a fast and scalable method; (2) it influences cluster granularity; (3) it is not misled by the edges that link different clusters; and (4) analysis of the algorithm has proven that there is an intrinsic relationship between the flow simulation process and the structures of the clusters in the input graph.

Spectral clustering

Continuity algorithms, as the name suggests seek the continuity of the data rather than looking for a centroid like classical clustering algorithms (Menendez *et al.*, 2014). Spectral clustering (SC) is a very popular continuity clustering method which is based on finding the best edge cut in the input graph. Spectral clustering uses the concept of similarity graphs and the information generated from the eigenvectors so the eigenvalues of the matrices can be generated and analyzed to find the best cut. Similarity graphs can be used to reformulate the clustering. Depending on the local neighborhood relationship between data points, there are different types of similarity graphs (Von Luxburg, 2007).

1. The " ϵ -neighborhood" graph: unweighted graphs where points with a pairwise distance smaller than the ϵ value.
2. The "k-nearest neighborhood" graph: two vertices v_i and v_j are connected if the later lies in the neighborhood of the vertex v_i .
3. The "Fully Connected" Graph: All the points with positive similarity are clustered together and edges are weighted by the similarity value s_{ij} .

The aim is to search for partitions in the data such that edges with high weights connects elements within each group while edges with low weights left outside the clusters connecting elements that belong to different groups (Von Luxburg, 2007). Parameter selection is critical to the quality of the clusters that are formed using these algorithms. The Laplacian matrix measures the difference in the value of a vertex from its neighbors in a graph. Laplacian matrices (also known as Kirchhoff matrices) are the most important part of spectral clustering algorithms. There are two different variants of Laplacian matrices: normalized and un-normalized that are used in the different spectral clustering algorithms. Given a graph G , with n vertices, its Laplacian matrix is defined by the $n \times n$ matrix $L(G) = D(G) - A(G)$, where $D(G) \rightarrow$ Diagonal matrix of vertex degrees and $A(G)$ is the adjacency matrix (Merris, 1994). The un-normalized Laplacian graph is defined as: $L = D - W$ where Matrix L satisfies several properties, such as L is symmetric and semi-definite (positive).

Fig. 8 Schematic diagram representing spectral clustering algorithm.

As spectral clustering seeks data continuity, it gives the best results when used for pattern recognition purpose. The use of the eigenvectors makes it a valuable tool for image processing (Fig. 8). The majority of spectral clustering algorithms minimize the interaction between dissimilar nodes to balance the size of the clusters (White and Smyth, 2005). All spectral clustering algorithms fall under three different categories (Verma and Meila, 2003):

1. Recursive Spectral Algorithms: The Recursive algorithms split the data into two halves based on an eigenvector and then these are recursively used to generate more partitions.
2. Multiway Spectral Algorithms: Multiple eigenvectors are used to do a multiway partition of the data.
3. Non-Spectral Algorithms: These are simple grouping algorithms used to cluster data in a short amount of time.

There are four widely used algorithms: (1) The Shi-Malik (SM) Algorithm (Shi and Malik, 2000); (2) Kannan, Vempla and Vetta (KVV) Algorithm (Kannan *et al.*, 2004); (3) Ng, Jordon and Weiss (NJW) Algorithm (Ng *et al.*, 2002); and (4) MeilPa and Shi Multicut Algorithm (MeilPa and Shi, 2001).

Speed and performance in clustering (SPICi)

SPICi was developed to analyze large networks (Jiang and Singh, 2010). It is a heuristic method that uses a greedy approach and builds clusters by starting from local seeds with a high weighted degree and adds nodes to maintain the density of the cluster. SPICi is based on a simple cluster expansion approach and uses various seed selection criteria along with different interaction confidence values. It is between 4 and 1000 times faster than other clustering approaches on biological networks and is one of the algorithms that is able to cluster large networks within a reasonable amount of time (Jiang and Singh, 2010).

The main goal of SPICi is to output a “set of disjoint dense subgraphs”. It uses the heuristic based greedy approach to build clusters which are expanded from the original seed pair of proteins. The density of a cluster is maintained over a set threshold value by adding only those unclustered nodes to the cluster that have a high support value. If the support value is not sufficiently high, nodes are removed from and the cluster.

Algorithm:

The algorithm is based on two parameters; (1) T_s : the support threshold and (2) T_d : the density threshold and consists of two main steps:

1. **Search**
 - i. Initialize a degree = V
 - ii. u extracted from DegreeQ with largest weighted degree
 - iii. If u has adjacent vertices then the second seed protein v is extracted from the vertices.
2. **Expand (u, v)**
 - i. Initialize a cluster $S = \{u, v\}$
 - ii. Initialize a CandidateQ that contains vertices neighboring u or v
 - iii. t is extracted from Candidate with highest support (t, S)
 - iv. Condition: Support (t, S) $\geq T_s * |S| * \text{density}(S)$ and
 $\text{Density}(S \cup \{t\}) \geq T_d$
Then, $S = S + \{t\}$

DegreeQ is a data structure and part of the priority queue which picks the seed proteins from which the clusters are built. CandidateQ are also part of the priority queue and are used to expand clusters.

Validation Criteria

Clustering algorithms depend on the features of the data and the input parameters. Clustering validity indices are used to determine the input parameters and evaluate the clusters. Validity indices are defined by: (1) compactness; and (2) separation (Liu *et al.*, 2010). Compactness measures how closely related objects in a cluster are. Compactness can be measured based on variance or distance. Some methods use variance as a variable to calculate the compactness of clusters, with lower variance indicating better compactness. Some methods use distance as a measure for compactness (e.g., maximum pairwise distance). Separation measures how distinct one cluster is from another. The minimum pairwise distances between objects in different clusters are widely used measures for measuring separation.

Validity measures are divided into two major categories (Rendón *et al.*, 2011): internal and external validity measures. The internal validity measures rely only on information in the data. They are used to evaluate the quality of the clusters without respect to any external information. External validity measures, on the other hand, rely on the external information and they know the “true” cluster number in advance, making them the best method for choosing the optional clustering algorithm for a specific dataset. The only setback is the requirement of additional information. Internal clustering validation can be used to choose the optimal clustering method along with the optimal cluster number without any additional information. In practice, it is difficult to find external information such as class labels, making external validation more difficult than internal validation.

Table 1 Widely used internal validity measures

Measure	Definition
1. Ball-Hall index Ball and Hall (1965)	$\mathcal{C} = \frac{1}{K} \sum_{k=1}^K \frac{1}{n_k} \sum_{i \in I_k} \ \mathbf{M}_i^{(k)} - \mathbf{G}^{(k)} \ ^2$ where, $\mathbf{M}_i^{(k)}$ = Observations in a cluster and $\mathbf{G}^{(k)}$ = Barycenter of the cluster.
2. Dunn Index (D) Dunn (1974)	$\mathcal{C} = \frac{\min_{1 \leq i \leq m} \delta(\mathbf{C}_i, \mathbf{C}_j)}{\max_{1 \leq k \leq m} \Delta_k}$ where, $\delta(\mathbf{C}_i, \mathbf{C}_j)$ is the intercluster distance between the clusters ($\mathbf{C}_i$ and $\mathbf{C}_j$)
3. Silhouette (S) index Rousseeuw (1987)	$\mathcal{C} = \frac{1}{K} \sum_{k=1}^K \frac{1}{n_k} \sum_{i \in I_k} \frac{\min_{k' \neq k} \frac{1}{n_{k'}} d(\mathbf{M}_i, \mathbf{M}_{k'}) - \frac{1}{n_k} \sum_{i' \in I_k} d(\mathbf{M}_i, \mathbf{M}_{i'})}{\max \left(\frac{1}{n_k} \sum_{i' \in I_k} d(\mathbf{M}_i, \mathbf{M}_{i'}), \min_{k' \neq k} \frac{1}{n_{k'}} d(\mathbf{M}_i, \mathbf{M}_{k'}) \right)}$ Where, $d(\mathbf{M}_i, \mathbf{M}_{i'})$ = distance between the observations
4. Davies-Bouldin index (DB) Davies and Bouldin (1979)	$\mathcal{C} = \frac{1}{K} \sum_{k=1}^K \max_{k' \neq k} \left(\frac{\delta_k + \delta_{k'}}{2} \right)$ where, δ_k = mean distance of the points belonging to the cluster $\mathbf{C}_k$ to the barycenter $\mathbf{G}^{(k)}$
5. Calinski-Harabasz index (CH) Caliński and Harabasz (1974)	$\mathcal{C} = \frac{N-K}{K-1} \frac{BGSS}{WGSS}$ where, $WGSS = \sum_{k=1}^K \sum_{i \in I_k} \ \mathbf{M}_i^{(k)} - \mathbf{G}^{(k)} \ ^2$ and $BGSS = \sum_{k=1}^K n_k \ \mathbf{G}^{(k)} - \mathbf{G} \ ^2$
6. S_Dbw index Halkidi and Vazirgiannis (2001)	$\mathcal{C} = \frac{\frac{1}{K} \sum_{k=1}^K \ (\text{Var}(\mathbf{V}_1^{(k)}), \dots, \text{Var}(\mathbf{V}_p^{(k)})) \ }{\ (\text{Var}(\mathbf{V}_1), \dots, \text{Var}(\mathbf{V}_p)) \ } + \frac{2}{K(K-1)} \sum_{k < k'} \frac{\gamma_{kk'}(\mathbf{H}_{kk'})}{\max(\gamma_{kk'}(\mathbf{G}^{(k)}), \gamma_{kk'}(\mathbf{G}^{(k')}))}$ Where, $\gamma_{kk'}$ = density for a given point and $\mathbf{H}_{kk'}$ = midpoints of the clusters and $\mathbf{G}^{(k)}$ = Barycenter of the cluster
7. SD index Halkidi et al. (2001)	$\mathcal{C} = \alpha \frac{\frac{1}{K} \sum_{k=1}^K \ (\text{Var}(\mathbf{V}_1^{(k)}), \dots, \text{Var}(\mathbf{V}_p^{(k)})) \ }{\ (\text{Var}(\mathbf{V}_1), \dots, \text{Var}(\mathbf{V}_p)) \ } + \frac{\max_{k \neq k'} \ \mathbf{G}^{(k)} - \mathbf{G}^{(k')} \ }{\min_{k \neq k'} \ \mathbf{G}^{(k)} - \mathbf{G}^{(k')} \ } \sum_{k=1}^K \frac{1}{\sum_{k'=1, k' \neq k}^K \ \mathbf{G}^{(k)} - \mathbf{G}^{(k')} \ }$ Where, $\mathbf{V}_1^{(k)}$ = variance vectors and $\mathbf{G}^{(k)} - \mathbf{G}^{(k')}$ = distance between barycenters of the clusters.
8. Root mean square std dev (RMSSTD) Sharma (1995)	$\mathcal{C} = \left\{ \frac{\sum_i \sum_{x \in C_i} \ \mathbf{x} - \mathbf{c}_i \ ^2}{[P \sum_i (n_i - 1)]} \right\}^{\frac{1}{2}}$ where, $\mathbf{c}_i$ = center of the i -th center $\mathbf{C}_i$ and n_i = number of objects in $\mathbf{C}_i$ and P = attributes number of datasets D
9. Baker-Hubert Gamma index Baker and Hubert (1975)	$\mathcal{C} = \frac{s^+ - s^-}{s^+ + s^-}$ where, $s^+ = \sum_{(r,s) \in I_B} \sum_{(u,v) \in I_W} 1_{\{d_{uv} < d_{rs}\}}$ and $s^- = \sum_{(r,s) \in I_B} \sum_{(u,v) \in I_W} 1_{\{d_{uv} > d_{rs}\}}$

Internal Validation

Several validation measures have been proposed over the years. The internal validation measures have certain limitations. For example, noise in the data can affect the pairwise distance calculated between objects, which in turn affects the performance score of the clustering algorithm. The performance of the existing internal validation measures in different situations remains unknown. The validation measures depend on the type of data and its characteristics. There are several internal validity indices (Table 1), which are widely used to validate the clustering results.

Internal validation measures follow four steps to determine the optimal cluster number and the best partition (Liu et al., 2010):

- 1) Initializing the list of clustering algorithms that are applied to the dataset.
- 2) Using different combinations of parameters to get different clustering results for each of the clustering algorithms.
- 3) The internal validation index of each of the partitions obtained in the previous step is calculated.
- 4) The optimal cluster number and the best partition are selected according to the criteria.

External Validation

The external validation criteria are also based on statistical methods. User specific intuition is required while evaluating the clusters using the external validation criteria (Kovács et al., 2005). External criteria evaluate the cluster results based on a set of pre-specified

Table 2 Widely used external validity measures

	Measure	Definition
1.	F-measure Rendón et al. (2011)	$F(i, j) = \frac{2 \text{Recall}(i, j) \text{Precision}(i, j)}{\text{Precision}(i, j) + \text{Recall}(i, j)}$ where, $\text{Recall}(i, j) = \frac{n_{ij}}{n_i}$ and $\text{Precision}(i, j) = \frac{n_{ij}}{n_j}$
2.	The Folkes–Mallows index Fowlkes and Mallows (1983)	$C = \sqrt{\text{Precision} * \text{Recall}}$ where, $\text{Recall}(i, j) = \frac{n_{ij}}{n_i}$ and $\text{Precision}(i, j) = \frac{n_{ij}}{n_j}$
3.	Entropy Rendón et al. (2011)	$E = \sum_{j=1}^m \frac{n_j}{n} \sum_i p_{ij} \log p_{ij}$ where, p_{ij} =purity
4.	The Kulczynski index Kulczyński (1928)	$C = \frac{1}{2} (\text{Precision} + \text{Recall})$ where, $\text{Recall}(i, j) = \frac{n_{ij}}{n_i}$ and $\text{Precision}(i, j) = \frac{n_{ij}}{n_j}$
5.	Purity Rendón et al. (2011)	$\text{Purity} = \sum_{j=1}^m \frac{n_j}{n} * \frac{1}{n_j} \max_i (n_{ij}^i)$, where n_j =size of cluster 'j' and m is the number of clusters.

parameters that reflect the user's intuition about the clustering ([Halkidi et al., 2001](#)). Some of the most widely used external validity indices are listed in [Table 2](#).

Conclusions

With the remarkable continuous advancements in instrumentations supporting biomedical research, massive amount of various types data is generated at a rapid rate. It can be argued that progress in biosciences and healthcare will be measured for the most part by how well researchers will be able to take advantage of the available data. Analytical tools will play a significant role in that regard. With biological networks emerging as a natural way to model and arrange the available data, clustering techniques are bound to represent a major tool in analyzing biological data and in extracting new knowledge desperately needed for reaching new medical discoveries. In this study, we show that although many clustering algorithms are already available to bioinformatics researchers, the research question of how to cluster biological data is far from having a clear answer. No current approach is consistently superior for addressing the clustering problem for all types of biological data. Different methods perform better than others in clustering certain data types while optimizing specific criteria. Which clustering approach should be used to cluster a given set of biological data to extract specific pieces of knowledge remains very much a current and relevant research question in bioinformatics. In addition, the issue of how to assess the quality of the clusters obtained by clustering algorithms and validate the biological value of the knowledge they provide represents an even more challenging research question. Although our study attempts to identify the advantages and disadvantages of each clustering approach, more research is needed to answer these two questions.

Introduction

Biological pathways are an abstract representation methodology that is used to represent a certain number of biological events reactions, phosphorylation, catalysis, inhibition, deactivation, etc. that govern the normal or abnormal life cycle of the cellular machinery. Effectively, biological pathways can trigger a series of interactions among molecules in a cell that leads to the production of new molecules (such as fat or protein) or to change in the cell (turning genes on and off or spurring a cell to move). The activation of protein assembly is regulated by an intricate network of interactions among various molecules that lie into the cell, and with the outwards too (Ridley, 2011). Moreover, cells constantly receive signals from both inside and outside the body, which are prompted by such events as injury, infection, sun light, or even food. In order to fit and react to these signals, cells organize their actions sending and receiving signals through biological pathways. The molecules that comprise pathway interact together by means of signals to carry out their assigned tasks. The range of action of a biological pathway is not limited to the inside of the cell, in fact, a pathway can act with other pathways into its neighbourhood (signalling the start of a repair activity or meiosis) or on long distance (pathway product is a hormone that needs to move for long distances into the blood in order to reach the receptor target) (Hla, 2003). A vast number of pathways do not begin at the point i and finish at the point j . Indeed, several pathways have no real limits, and pathways often work in synergy to accomplish multiple tasks. When many biological pathways interact with each other, they produce a very intricate biological network as a result. Thus, biological pathways regulate the total activity of an organism. Therefore, it is important to emphasize that *biological pathways sometimes may function improperly*. When something goes improperly in a pathway, the result can be a disease such as: *cancer*, *diabetes* or *Alzheimer* (Antoni et al., 2006). Thanks to high-throughput analysis that allowed the investigation of global structures instead of the behaviour of individual molecules, it became possible to highlight and understand in a remarkable way, how these complex pathways networks work. Understanding how pathways work is very important, since, it is now becoming increasingly evident that the connection between pathways and diseases are fashioned at multiple interconnected levels. Biological pathways information are available through a significant number of databases ranging from databases manually created by human curators to large databases, comprising a vast number of pathways, created through biological experiments, or inferred electronically by using Natural Language Processing (NLP) techniques, or text/data mining from data coming from the scientific literature. Because of the differences in size, quality, and property, it is essential to use the right database that better fits the user's purpose. Reason for which at nowadays exist public and private biological pathway databases serving as repositories of the current knowledge on pathways (Cerami et al., 2010; Rahmati et al., 2017; Croft et al., 2010; Schaefer et al., 2008; Kanehisa and Goto, 2000; Goto et al., 2002; Bader et al., 2006; Mi and Thomas, 2009). Coordinated efforts are now being made to provide tools to consolidate, visualize, standardize and handle with these large amount of available data. This should make the data easily available to further analysis such as to attempt the decoding of other unknown principles of known and unknown biological pathways as well as new types of biological pathways. The complexity of biological systems are orchestrated by several interacting molecular types, comprising, DNA, RNA, proteins and other small molecules, yielding as result a network. The main goal of system biology is to map these networks in a way that could provide new insight of cell biology at the molecular level. Even though high-throughput methodologies such as Mass-Spectrometry, Next Generation Sequencing (NGS), DNA-microarray, SNP-microarray, Genome Wide Association Studies (GWAS) and so on, can provide huge amount of data per each single experiment, by simultaneous monitoring hundred thousand of gene, proteins or molecules per time, uncover the underlying network of physical interaction remain a tough challenge. The most advanced high-throughput technology such as microarrays lets researchers observe mRNA concentrations in a cell population on a genome wide scale. Other high-throughput techniques, such as transcription factor binding microarrays (ChIP-chip), compound library screening, protein and metabolite profiles, and genome-wide identification of protein-protein interactions and post translational modifications, are less developed but growing fast. Researchers can also employ reliable quantitative data from lower throughput methodologies such as functional reporter-gene assays. Despite the low data produced per single experiment, those methodologies may be applied even to the analysis of large biological networks, since these smaller but better-understood data can provide critical clue on the mechanisms involved into the phenomena under investigation. Other significant evidence comes from evolutionary conservation; a property often exploited in other areas of biological research, where known preservation of interaction in some species may be used to predict its existence in another species. Most pathway inference approaches to address a particular layer of biochemical interactions, such as transcriptional (protein-DNA), signalling protein-protein, protein-DNA, protein complex (protein-protein), or metabolic (protein-metabolite) interactions. Different layers can have a different network character of gene expression networks. For example, metabolic networks tend to be resistant to change, they are constrained by a few co-factors that influence myriad of reactions, and the corresponding graphs have many branches and loops. Graphs are a mathematical formalism that makes it possible to represent the interactions among objects. Biological networks are often represented as graphs, with "edges" connecting "nodes." (Pathway representation by means of graph is described in the next sections). Researchers are using several different algorithms to try to infer the possible structure of very different biological and artificial networks, and define some metrics with which to evaluate the reliability of the produced models represented by means of a graph. For example, one of the

most common problems that many molecular and cell biologists face in their research is: *I have a protein of interest but don't know its structure/function* (Roy *et al.*, 2010; Rost and Sander, 1993). Even though researchers have proposed several algorithms for network prediction, reconstruction, integration, consolidation, comparing are quite difficult tasks from point of view of the graph algorithm performance. Some of these difficulties arise due to these reasons including:

- heterogeneous source of data, i.e., high-throughput data with high noise or poorly validate and poor accurate data;
- it is difficult to explore biological networks within a specific cellular/molecular context, because network topology and features change changing the context;
- assessment requires the developing of errors balancing methodologies in predicting interacting that are not known; and
- common problem belonging to graph theory are known to belong to the NP-complete class of problems. Such as, finding the largest complete subgraph in a given graph. Algorithm used to figure out evidence comes from evolutionary conservation.

A biological pathway is a series of interactions among several molecules in a cell, i.e., DNA, RNA, proteins, and metabolites that lead to a certain product g.e. a change in a cell, by triggering the synthesis of new molecules, or turning genes on and off. Thus a rough classification of biological pathways could produce three classes of pathways involved in metabolism, in the regulation of gene expression and in the signals transduction.

Biological Pathway Classification

Advances in high throughput technologies have enabled the discovery of many pathways, however, many remain unknown. In fact, it is still a great challenge to identify and classify the missing pathways. Since pathways control almost the totality of biological events of an organism, it is better to describe pathways as a class rather than list them individually. Pathways can be divided into these main classes: *Metabolic*, *Gene Regulation* and *Signal Transduction*.

- *Metabolic Pathways*: refers to pathways that regulate the chemical reactions carried out by a cell in order to transform food into energy. Carbohydrates, lipids, and proteins are the major constituents of foods and serve as fuel molecules for the human body. The digestion (breaking down into smaller pieces) of these nutrients in the alimentary tract and the subsequent absorption (entry into the bloodstream) of the digestive end products make it possible for tissues and cells to transform the potential chemical energy of food into useful work.
- *Gene Regulation Pathways*: consist of pathways responsible for the activation (or deactivation) of genes (on, off). Gene regulation is vital for every organism, because genes contain the key information for all the processes in the cell, including protein production. Moreover, proteins are key components needed to carry out nearly every task in each living organism, including the development of muscles, organs etc.
- *Signal Transduction Pathways*: are pathways capable of delivering a signal from a source to a destination. In more details, they move a signal from a cell to the target receptor located on the cell membrane. Every receptor is compatible only with specific signals. The interaction between receptor and signal, establishes a communication channel allowing the signal to travel through the cell by means of specialized proteins to trigger a specific action in the cell.

The classification can be useful in the process of discovering new pathways to predict functions of pathway. The recognition of a pathway is based on the identification of constituents involved in it, that can provide clues about the pathway working principles and thus, the pathway type. Therefore, highlighting out what pathway is involved in a disease, and detecting which components of the pathway exhibit a wrong behaviour, may lead to more personalized strategies for diagnosing, treating and preventing disease.

The approach of personalized treatments is useful to tackle complex diseases like cancer, where: *urgency is an important issue*. The ability to define an efficient treatment, without try it, allows to get better results for the patient, than trying some drugs and discovering only after some time whether the treatment worked or not, with the possibility that during this time the patient would die.

Model for Biological Pathways

Graphs are a mathematical formalism that makes it possible to represent the interactions among objects. Biological networks are often represented as graphs, with "edges" connecting "nodes." Graphs are quite simple, and it is straightforward to describe and analyze interacting objects, for example, the friendship between people in a social network. Although its simplicity graphs need to be extended to be the ideal tool to represent biological pathways. An extension of graph should take in to account the kind of biological network that should be represented. For example, to represent Protein Protein Interaction Network (PPI), the simple graph is the ideal formalism to convey interaction among proteins, and the edges have a more obvious meaning, indicating for instance that two proteins have been shown to form a complex in laboratory assays. For example, in molecular interaction graphs, the nodes represent genes or gene products and the edges represent specific interactions. Whereas, in a protein-DNA network, an edge may account for the binding of a transcription factor to a promoter region, while in a PPI network it might represent a documented evidence of co-immunoprecipitation or a two-hybrid interaction. A more robust formalism to

graphically express metabolic pathways arises, making necessary extend the graph in order to introduce different types of edges able to deal with several specific situations. In detail, regulatory pathway should be represented as a directed graph or digraph, where the vertices represent proteins and the arcs represent the relations between the corresponding proteins. The relation between two proteins has a direction. Because protein p_1 , can regulate protein p_2 , while p_2 cannot always control p_1 . A digraph represents nodes and edges with optional data, even known as attributes. In a digraph, self-loops are allowed, but multiple edges between the same two nodes are not, i.e., n_1 and n_2 there can be only one edge. Metabolic pathways could be represented by using bipartite graphs. In a bipartite graph, there are two types of nodes, one for compounds and one for reactions, with the edges representing the input-output relationships between reactions and compounds. In a bipartite graph, edges connect compounds to reactions (for substrates) or reactions to compounds (for products), but there are no edges between two reactions or between two compounds. Signalling pathways are conveyed as multi-graphs, where nodes represent proteins and edges represent pairwise interactions between proteins. In particular, in a directed graph, an undirected edge between nodes n_1 and n_2 is replaced by two directed edges (n_1, n_2) and (n_2, n_1). The edges are regularly directed in signalling pathways, such as when a kinase phosphorylates a substrate.

Pathways Data

The number of pathway databases is growing quickly in recent years. This is advantageous because biologists often need to use information from many sources to support their research. But on the other hand, each database has its own representation conventions and data access methods, making data integration from multiple databases a huge challenge. This calls for a need to define an unique file format that makes possible to integrate together data from various databases. Pathway data are encoded using different type of file formats such as: structured file as: XML, OWL, RDF and XML-based, psimi-xml; or unstructured text files. The most used structured file format are: *BIOPAX – LEVEL 1,2,3* (Cite Biological and Medical Ontologies: Biological Pathways Exchange (BioPAX) in Encyclopedia of Bioinformatics and Computational Biology – BIOPAX 2017), *PSI-MI*, *BIOPAX*, *SBML* (Cite Standards and Models for Biological Data: SBML in Encyclopedia of Bioinformatics and Computational Biology 2017), *PSI-MI*, *SBML* and *CELLML*. Whereas, the most used unstructured file format are: MITAB, CSV (Comma Separated Values), psimi-tab tab delimited. With the following peculiarity: sometime the same information can be expressed in different ways, despite is used the same file format to encode the data, making the analysis process hard to achieve. The high level of heterogeneity among available pathway data, making automatic data analysis ineffective. An attempt to reduce the high level of heterogeneity is adopted by the BIOPAX (Demir *et al.*, 2010) consortium. BIOPAX is trying to impose itself as standard to represent biologicals pathways data. *BIOPAX -Biological Pathway Exchange-*, is a meta language defined in OWL DL and is represented in the RDF/XML format. BioPAX aims is, to facilitate the integration and exchange of data maintained in biological pathway databases, by means of a unique way to represent data. Traditionally, integration and comparison of different data from a syntactic and semantic point of view, has always been a challenge in the field of Bioinformatics. The latest version is BioPAX Level 3 and it is the recommended version. Since that, the BioPAX Level 3 supports metabolic pathways, signalling pathways (including states of molecules and generic molecules), gene regulatory networks, molecular interactions, genetic interactions. It is not fully backward compatible with Level 1 and 2. At now, BIOPAX is used to represent biological pathway data, on the correct way to became standard.

Pathways consist of a large number of elements that interact amongst themselves to carry out a collaborative biological action. This huge interaction network can be represented using the graph formalism, where every biological element such as protein, complexes, DNA molecule, RNA molecule etc., can be represented as vertices, and catalysis can be represented as edges (interactions). Currently, a standard graphical representation of a single biologicals elements does not exist, and there is a lack in uniformity in graphical form. Therefore, the same element can be displayed in different ways by different visualization tools. A good solution could be to define a uniform graphical representation of biological elements since, there is need to define an unique way to represent visually a biological element, if it is compared with computational analysis. The graphical representation can be achieved by, through the definition of unique graphical constraints able to convey graphically the biological meaning (Agapito *et al.*, 2013; Pastrello *et al.*, 2013). Involving domain experts – biologist, oncologist – asking what is the best way to convey the biological meaning graphically of each kind of element.

The visualization of biological elements is not a simple task as it might seem, because each element has a specific meaning related with the biological context. Despite the limited number of biological element known, the high content of information related with each one, makes data analysis very hard to face (Cite Visualization of Biological Pathways in Encyclopedia of Bioinformatics and Computational Biology 2017). Due to these problems a further effort it is required in order to develop algorithms (*parsers*) able to exploit biological information to represent opportunely every biological elements. A protein can have more than one meaning in relation with the biological context. Thus, there is need of algorithms able to correctly infer what a specific element means, in order to be able to represent it. The greatest effort in the representation of biological element is related with the management of input data, due the high semantics and syntax complexity that characterizes the data. Thus, understanding the meaning of the data to analyze, is essential in order to properly represent the data. It is coming clear that, before to be able to represent graphically the information, it is necessary a huge effort to parse correctly the information into the input data, in order to create the opportune data structures necessary to store the normalized data that will guarantee an uniformity in the visualization step. Successively, the graphical representation -how to arrange the data-, is accomplished by mean of layout algorithms, with the goal to represent graphically: biological interaction networks (Agapito *et al.*, 2013).

Fig. 1 The citric acid cycle is an example of metabolic pathway.

Metabolic Pathways

Metabolic pathways described the context of the whole cell metabolism. A cellular metabolic reaction network is a collection of enzymatic reactions and transport processes that serve to refill and reduce the relative amounts of individual metabolites. Making it possible the analysis of the structural design and capabilities of the metabolic network. Metabolism is defined as a complex system of chemical and physical processes involved in the maintenance of life. Metabolism comprises a vast collection of enzymatic reactions and transport processes able to convert organic compounds into the several of molecules essential to support cellular life. An example of metabolic pathways is presented in [Fig. 1](#).

The set of reactions and consequently the pathways that a metabolic network holds determine the architecture and topology of the network. The whole set of reactions is controlled by using sophisticated biological control schemes, making it possible to achieve the metabolic objectives throughout the cell's metabolic network. Cells to take advantage of the production capabilities of the metabolic networks, cells have to figure out a method to control the arrangement of the involved molecules and the pathways that determine these capabilities. The functional unit in metabolic networks is the enzyme or gene product, performing a particular chemical reaction or promoting a moving process. Control of metabolism includes regulation of individual reactions at several levels from enzymatic (activation/inhibition) until to the regulation of the genes transcription functions. The cells by physically controlling the single functional units involved in the metabolic network, they can control their metabolic pathways. Thus, trying to understand the regulatory mechanisms achieved by the cell to control the metabolic networks, will allow the analysis and understanding of metabolic pathways.

Due to the complexity of metabolic networks, the main difficulty to represent graphically metabolic pathways concerns with the identification of the whole model comprising the appropriate compounds (metabolites). The major obstacle to represent metabolic pathways is that multiple metabolic pathways could be available, that can link the substrates to the target metabolites due to the large number of potential routes. In addition, without a specific goal and automated ranking function, finding the most efficient pathway could be quite difficult, or could require the assembly and screening of an unrealistically large number of constructs. For this purpose, several computational tools have been developed, that consider the properties of enzymes, intermediate metabolites, metabolic flux and the host cell to support researcher in the assembly and visualization of the metabolic pathways. Thus, the use of computational tools can speed up the analysis of metabolic networks. Highlighting in an easy way all the possible pathways that can lead to the production of a given compound. Thus, the identification of the best variants of candidate compounds, i.e., enzymes, small molecules, may lead to an increase in pathway efficiency.

Computational resources not only help to retrieve information about metabolic pathways but also provide tools for exploring metabolic pathways to highlight the most relevant information and at the same time producing a networks representation able to simplify the visual analysis.

Metabolic Pathway Visualization and Analysis Tools

In this section are listed some of the most known and used tool in the analysis and visualization of Metabolic Pathway. Further information about other tools (not listed in this section) can be found at the follows web address <https://omictools.com/search?q=metabolic+pathway>.

- **BioNetGen** (Faeder *et al.*, 2009): Is an open source package for the specification and simulation of rule-based models of biochemical systems, comprising signal transduction, metabolic, and genetic regulatory networks. The software and the documentation are available at <http://bionetgen.org> web address. BioNetGen is easy to install and runs on Linux, Mac OS X, and Windows operating systems. Moreover, an online version of BioNetGen is available at the following web address: <http://vcell.org/bionetgen>. BioNetGen has been used to model a variety of biological processes. Models are written in BNGL (BioNetGen language), a text-based modeling language. BioNetGen can export model in SBML or MATLAB formats.
- **iPAVS** (Sreenivasaiah *et al.*, 2012): is an integrated biological pathway database designed to support pathway discovery in the fields of omics sciences and systems biology, providing a selection of highly-structured manually curated human pathway data for biologists. In the current version, iPAVS integrates several human pathways including metabolic, signaling, disease-related and drug-action pathways. Furthermore, iPAVS come with a very easy to use web interface allowing biologists to browse and search pathway resources and provides tools for data import, management, visualization, and analysis to support the interpretation of biological data in light of cellular processes. iPAVS web interface implemented advanced functionalities to make complex pathway analysis tasks and visualize the results. As well as, the simple and intuitive design make it possible to use all the advanced iPAVS features even too by everyone. iPAVS web interface and the relative user documentation are available at the following web address <http://ipavs.cidms.org>. Users can export results by using the Systems Biology Graphical Notations (SBGN) and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway notations as well as are used for the visual display of pathway information. Whereas, networks visualization is obtained through Scalable Vector Graphics (SVG).
- **iPath** (Letunic *et al.*, 2008; Yamada *et al.*, 2011): interactive Pathways Explorer (iPath) is a web-based tool for the visualization, analysis and customization of the various pathways maps. Current version provides three different global overview maps: i) metabolic pathways constructed using 1464 KEGG pathways, and gives an overview of the complete metabolism in biological systems; ii) regulatory pathways: 22 KEGG regulatory pathways; and iii) biosynthesis of secondary metabolites: contains 58 KEGG pathways involved in biosynthesis of secondary metabolites. In order to access iPATH web interface, users have to use a web-browser compatible with Adobe Flash plug-ing. The iPATH's user interface present a layout based on tabs between which the users can interact and analyze the visualized data (called Map). In iPath, maps (results) can be exported in various output formats among which: Portable Network Graphics (png), Encapsulated Postscript (eps), Postscript (ps), Portable Document Format (pdf), and Scalable Vector Graphics (svg).
- **Arcadia** (Villger *et al.*, 2010): is a software tool, offering multiple perspectives on the same data, with a focus on navigation. Enabling the interactive exploration on various kind of pathways, visualisation software provides considerable assistance in making sense of complex networks. Arcadia has been designed specifically to provide relevant visualisation options for metabolic pathways, avoiding user to do adjustments on the layouts computed. Arcadia is written in C++ based on the following open-source libraries: i) "LibSBML" an interface to SBML pathway files; ii) "Boost Graph Library" an efficient graph structure library; iii) GraphViz classic layout algorithms; iv) "libavoid" dynamic edge routing library; and v) "Qt" library for the developing of the Graphical User Interface. It is Cross-platform, the code can be compiled to run on Mac, UNIX or Windows systems. Arcadia can be downloaded at the following web address <https://sourceforge.net/projects/arcadiapathways/>. Results can be exported in SBML and SBGN formats, or as vector image in the following formats SVG, PDF, PS.
- **UBViz** (Second, 2005): is a software tool to explore matabolic pathways in 3D space. UBViz is available for the download after free registration at the follow web address <https://www.complex.iastate.edu/download/UBViz/download.html>. UBViz provides and performs the 3D layout algorithm locally on metabolic pathway based on the provided logical descriptions of the pathway. UBViz is a standalone application written by using C++, and it is easily installable by end-users. UBViz graphical interface developed using wxWidgets (see Relevant Websites section), an open-source multiplatform graphical user interface (GUI) toolkit. Node and edge 3D layout is obtained by using a GraphViz module based. Finally, results are rendered on the screen by OpenGL (see Relevant Websites section). Data can be directly downloaded from KEGG by exploiting the FTP functionalities of UBViz or loaded local data stored in the local disk.
- **COPASI** (Hoops *et al.*, 2006; Sahle *et al.*, 2006): is a software application for simulation and analysis of biochemical networks and their dynamics. COPASI can be download at the following address <http://copasi.org/Download/> and it is provided under the Artistic License 2.0. COPASI is a stand-alone program that supports models (reactions) in the SBML standard and can simulate their behavior using ODEs or Gillespie's stochastic simulation algorithm. COPASI's GUI interface is developed to visualize models, with tables for reactions, species, compartments, etc.; several number of network diagrams; the full set of differential equations; these can be exported in Latex or MathML formats. COPASI can perform several simulation either with stochastic kinetics or with differential equations, by implementing several algorithms. Furthermore, models can be analyzed and modified with a large set of available methods. COPASI can import and export models in the SBML format (levels 1 to 3). Models can also be exported in XPP format, Berkeley Madonna format, and as C code (in addition to MathML and Latex).

Table 1 conveys a graphically overview of the features available in each tool listed in this section.

Metabolic Pathways Databases

Comprehensive representations of metabolic pathways have been developed, which requires huge effort and would benefit from information stored in databases and from automatic retrieval and integration methods. Thus, the systematic collection of pathway

In the table OSC, Operating System Compatibility indicates in which operating system the tool is supported; FFS, File Format Supported indicates the approved file format for loading/exporting; CSk, Computer Skills refers to the know-how necessary to use the tool; RU, Restriction To Use specifies the scope where is allowed to use the tool; AA Available Applications indicates the types of available tools; V, Visualization specifies the type of support data visualization; finally A, Analysis conveys the type of analysis capability offered by the tool.

information in the form of pathway databases is crucial. Here is reported a succinct list of the most known metabolic pathways databases.

- **BioPath** (Schreiber, 2002): is a database of biochemical pathways that provides access to metabolic transformations and cellular regulations derived from the Roche Applied Science "Biochemical Pathways" wall chart. In the current version BioPath contains about 14,000 chemical structures, 3900 biochemical transformations (reactions), from the following organisms: prokaryotes, plants, yeasts and animals. Provides the following features, structures available as connection tables, atoms of substrates and products annotated by atom-atom mapping numbers, 3D coordinates of small molecules generated by CORINA Classic and so on. BioPath is freely available for academic users, but requires a license for commercial use, at the follows web address <https://www.mn-am.com/databases/biopath>.
- **HumanCyc** (Romero *et al.*, 2004): is a bioinformatics database that describes the human metabolic pathways and the human genome. By presenting metabolic pathways as an organizing framework for the human genome, HumanCyc provides the user with an extended dimension for functional analysis of Homo sapiens at the genomic level. HumanCyc encoded data by using the BioPAX and SBML data formats. HumanCyc is available at <https://humancyc.org> only after a valid license has been purchased.
- **KEGG** (Kanehisa and Goto, 2000): is a database of metabolic pathways from multiple organisms. KEGG is accessible through web browser at <http://www.kegg.jp/kegg/>. AS well as KEGG provide API (application programming interface) allows customization of KEGG-based analysis. KEGG API is provided for academic use by academic users belonging to academic institutions. KEGG data are encoded by using xml data format.
- **MetaCyc** (Caspi *et al.*, 2007): is a metabolic pathway database contains pathways from over 2816 different organisms. MetaCyc describes metabolic pathways, reactions, enzymes, and substrate compounds. The MetaCyc data were gathered from a variety of literature and on-line sources, and contain citations to the source of each pathway. MetaCyc allows user to download in the following formats: BioPAX, Pathway Tools attribute-value, Pathway Tools tabular, and SBML formats respectively. MetaCyc is free only for academic users at the follows address <https://metacyc.org>.
- **SABIO-RK** (Wittig *et al.*, 2011): SABIO-RK is a curated database that contains information about biochemical reactions, their kinetic rate equations with parameters and experimental conditions. SABIO-RK web interface can be accessed via web-base user interfaces at the following web address <http://sabio.villa-bosch.de>. SABIO-RK can be automatically accessed via RESTful Web Services. The Web Services allow the direct SABIO-RK data access by other tools or systems biology modelling platforms. The output of this Web Services search is available in different formats (e.g., SBML, XML). The user guide where it is explained how to use RESTful API and how to create request are available at the following web address <http://sabio.villa-bosch.de/layouts/content/docuRESTfulWeb/manual.gsp>. data can be exported in spreadsheet, SBML or BioPAX format. Moreover, spreadsheet allows to export the data in a table format (xls or tsv).

Table 2 conveys a graphically overview of the features available in each database listed in this section.

Gene Regulation Pathways

Gene Regulation Pathway explicitly represent the causality of developmental processes. They regulate the expression of thousands of genes in any given developmental process. By understanding the interactions in these networks, can be highlighted in a

Fig. 2 The activator with bound ligand stimulates transcription, as an example of gene regulation pathway.

remarkable way the mechanisms of diseases that occur when these cellular processes are or not working properly. An example of regulation pathway is depicted in [Fig. 2](#).

They are essentially hardwired genomic regulatory codes, the role of which is to specify the sets of genes that must be expressed in specific spatial and temporal patterns ([Davidson and Levin, 2005](#)). In the last decade, gene regulatory network/pathway have brought a lot of interest, thanks to the recent advancements in genomics and computational biology because are enabling the construction of large-scale models of gene regulatory networks. High-throughput methodologies such as automated sequencing, gene-expression arrays, and yeast two-hybrid assays, examining different features of the gene-regulatory system through genome-wide datasets, producing a vast quantity of data for each single experiment, bringing to light the mechanisms that underlie the gene regulatory pathways and, thus the necessity of automatic methods able to deal with this enormous amount of data, to infer the structure and interactions of gene regulatory pathways arise. At this regard, several statistical and machine-learning methods have been proposed to infer gene regulatory pathway from gene expression data, as evidenced by the following papers ([Liang et al., 1998](#); [Butte et al., 2000](#); [Basso et al., 2005](#); [Pache and Aloy, 2012](#)). In particular, in the work ([Emmert-Streib et al., 2014](#)) authors state that: gene regulatory pathways because are inferred from mRNAs data provide information about regulatory interactions between regulators and their potential targets; gene- gene interactions, and potential protein-protein interactions (e.g., in a complex) ([de Matos Simoes et al., 2013](#)). Because a gene regulatory pathway can potentially describe many kinds of physical, biochemical interactions among genes and gene products ([de Matos Simoes et al., 2013](#)), the assessment of inferred networks is an

essential and complex topic. Networks are complex structures able to model different kinds of features of biological systems. Because biological networks are inferred, the quality of inferred biological networks has to be assessed. The main problems in the assessing of biological inferred network are the definition of a methodology able to detect the *true* interactions also known as gold standard. Gold standard search is addressed by validating interactions functional databases or previous literature (Kanehisa and Goto, 2000; Kotlyar *et al.*, 2016). The main drawback of this approach is that, although the set of known interactions might be large, many of them might not be relevant to the biological conditions under investigation. For these reasons, define a methods and algorithms able to qualitatively assess the accuracy of the obtained network by using the gold standard. Various modelling methodology have been developed for gene regulatory network. The available methodologies used to represent gene regulatory pathways or networks can be classified into three main class: The first-class contains the logical models. Logical models describe regulatory networks qualitatively, providing to the user a basic qualitative idea on how several functionalities of a given system work in an orchestration fashion to accomplish some biological tasks. The second-class contains the continuous models; continuous models are mathematical formalism able to deal with continuous data, i.e., exact molecular concentrations at a particular instant time. For example, to simulate the effects of a particular drug on cancer cells under different active ingredient concentrations, users must use continuous models with a fine-grain resolution. The third class comprises single molecule level models. The single molecule level model describes components (genes) by using stochastic representation, and consequently, allowing to user to get an idea of why should be present different behaviors, even starting from the same initial conditions. The fourth class includes hybrid models. Hybrid models have been promoted to describe both, discrete and continuous aspects in one model. Because in the real world both continuous and discrete elements are present at the same time. For example, gene expressions are represented as continuous values, whereas the binding of a molecule with a receptor is expressed as a discrete event (bound or unbound). The modeling techniques used to represent gene regulatory pathway comprises the following models. *Logical models* are based on a discrete logic modeling methodology as described in Glass and Kauffman (1973), Thomas (1973). Genes, proteins and small molecules in logical models, are represented by using local state information, as discrete information at each instant. Temporal system evolutions happen in a synchronized way and are described as discrete time steps. Boolean networks are described by means an oriented graph G . A graph G is a mathematical formalism able to describe interaction among object (Fauré *et al.*, 2006). A graph G is defined as a couple $G=(V, E)$ where V is the set of boolean vertex vi . Whereas, E is the set of boolean edges that is if exist an edge between the node vi and its parent nodes in G . And at a given time the state of all the nodes represent the state of the network. Probabilistic boolean networks are an extension of the probabilistic network able to deal with uncertainty in the synchronization of regulatory events (Shmulevich *et al.*, 2002a,c,b). Bayesian networks are represented as an annotated directed acyclic graph $G(V, E)$, where the nodes, $\{vi \in V\}$, are random variables denoting genes' expressions, and the edges indicate the reliances among nodes. The random variables are obtained from conditional probability distributions $P(vi|Pa(vi))$, where $Pa(vi)$ is the parents set of each node (Kim *et al.*, 2004; Zou and Conzen, 2004). Continuous models, using real value parameters over an ongoing time scale, allow a straightforward comparison of the global state and experimental data. Linear models allow considering a biological system as a state machine, where the change in internal state of the biological system depends on the current internal state plus any external conditions (De Jong *et al.*, 2004; Hecker *et al.*, 2009). Allowing a high level of abstraction and efficient inference of network structure and regulation functions. For example, linear models are the perfect tool to describe the concentration of mRNA – representing the internal state of a cell. The simplest form of a linear model is reported in Eq. (1).

$$X_i(t + \Delta t) = \sum_k Y_{ik} X_k(t) \quad (1)$$

Where in Eq. (1) $X_i(t + \Delta t)$ is the expression level of the i – th gene at time $(t + \Delta t)$, and Y_{ik} represents the influence of the j – th gene on the i – th gene.

Gene regulatory networks can be encoded by using differential equations systems (Sakamoto and Iba, 2001; Chen *et al.*, 1999). Differential equations allow to better describe the system dynamics, by explicitly modeling the changing of the states (molecules) over the time. The simplest form of a equations system is conveyed in Eq. (2).

$$\begin{aligned} g_1(t + \Delta t) - g_1(t) &= (w_{11}g_1(t) + \dots + w_{1n}g_n(t))\Delta t \\ &\vdots \\ g_n(t + \Delta t) - g_n(t) &= (w_{n1}g_1(t) + \dots + w_{nn}g_n(t))\Delta t \end{aligned} \quad (2)$$

Where in Eq. (2) $g_i(t + \Delta t)$ is the expression level of i – th gene at time $(t + \Delta t)$, and w_{ij} is the weight indicating how much the level of the i – th gene is influenced by j – th gene, with $(i, j = 1, \dots, n)$.

Single molecule level models allow representing regulatory networks by using stochastic modeling, because the amount of regulatory molecules is often low (Ross *et al.*, 1994; Elf *et al.*, 2007; Schütz *et al.*, 1997). Experimental assays demonstrated the stochastic behavior of the processes of transcription and translation (Shea and Ackers, 1985).

Hybrid models have been developed to describe discrete and continuous aspects into a single model. Examples of hybrid models applied to gene regulatory pathways have been presented in Matsuno *et al.* (2000), Xu *et al.* (2007).

For further information on the representation of the methodologies, regulatory pathway gene can be found in the following papers (Karlebach and Shamir, 2008; Vijesh *et al.*, 2013).

Gene Regulatory Pathways Visualization and Analysis Tools

In this section are listed some of the most known and used tool in the analysis and visualization of gene regulatory pathway. Further information about other tools (not listed in this section) can be found at the follows web address <https://omictools.com/gene-regulatory-networks-category>.

- **Sig2GRN** (Zhang *et al.*, 2016): is a software tool linking signaling pathway with gene regulatory network for dynamic simulation. As a software tool for modeling cellular dynamics, Sig2GRN can facilitate studies in systems biology by hypotheses generation and wet-lab experimental design. Sig2GRN is wrote using the Java programming language, and is available as Cytoscape Plugin. Feature that makes Sig2GRN compatible with Linux, Windows and MacOSX operating systems. The plugin is freely available at the following web address Availability: <http://histone.scse.ntu.edu.sg/Sig2GRN/>. The package contains the executable components to be copied into the Cytoscape plugins directory, and a test network with which try the software.
- **ARACNe** (Margolin *et al.*, 2006): Algorithm for the Reconstruction of Accurate Cellular Networks - ARACNe is available as a Cytoscape app that is integrated in the Cyni Toolbox panel. ARACNe plugin does not require to be installed but should just copied into the Cytoscape plugins folder. ARACNe documentation and support are available at the following web address <http://califano.c2b2.columbia.edu/aracne>. ARACNe is available under non-commercial license agreement for the download at the follows address <http://califano.c2b2.columbia.edu/aracne-license> after free registration. ARACNe is available to download as software compatible with all the current operating systems such as Linux, Mac OSX and Windows.
- **Discrete Dynamics Lab (DDLab)** (Wuensche, 2010): is an interactive graphics software for creating, visualizing, and analyzing many aspects of Cellular Automata (CA), Random Boolean Networks (RBNs), and Discrete Dynamical Networks (DDNs) in general, and studying their behavior, both from the time-series perspective - space- time patterns, and from the state-space perspective Attractor Basins. DDLab is free (open source) software under the GNU General Public License. However, institutional users (commercial or educational) are required to register and pay a registration fee. Personal users are also encouraged to register. DDLab is available as web-based application at <http://www.ddlab.com>. The user guide and manuals are available at the following address http://www.ddlab.org/download/dd_manual_2016/.
- **FERN** (Erhard *et al.*, 2008): Framework for Evaluation of Reaction Networks - FERN - is a fast, extensible and comprehensive framework for the stochastic simulation and analysis of chemical reaction networks written in Java. It includes state of the art algorithms for stochastic simulation and a powerful visualization system based on "gnuplot" and Cytoscape. FERN is freely available for download at the follows web address <https://drupal.bio.ifi.lmu.de/FERN/> section download and requirements for download additional features. At the same address can be found user guides, example and API to extend FERN.
- **GRENDL** (Haynes and Brent, 2009): Gene REgulatory Network Decoding Evaluations tool is an open and extensible software toolkit that generates random gene regulatory pathways according to user-defined constraints on the network topology and kinetics. GRENDL in the current release provides Kinetic regulatory functions such as Hill Kinetics and Michaelis-Menten with combinatoric interactions between regulators. Experimental design types supported: genetically diverse population samples, knockouts, overexpression and time course with external stimuli perturbations. The current version of GRENDL is wrote in C++ and is freely available for download at the follows web address <http://mblab.wustl.edu/software.html> section GRENDL.
- **FastNCA** (Chang *et al.*, 2008): Fast network component analysis -FastNCA- for gene regulatory network reconstruction from microarray data. FastNCA algorithm is coded by means of MATLAB, and it is available as MATLAB plugin, freely available for download at the following web address <http://www.ee.ucla.edu/~riccardo/NCA/nca.html>.
- **BNFinder2** (Cooper and Herskovits, 1992): is a software tool for learning Bayesian networks, allowing users, to build Bayesian network starting from experimental data. The current version of BNFinder2 is available for download from Python Package <https://pypi.python.org/pypi/BNfinder>. User's manuals and tutorial are available on the follows web site <http://bioputer.mimuw.edu.pl/software/bnf/>. BNFinder2 allows user to export data in the following formats sif (Simple Interaction File), and bif (Bayesian Interchange Format).

Table 3 conveys a graphically overview of the features available in each tool listed in this section.

Gene Regulatory Pathways Databases

Comprehensive representations of gene regulatory pathways have been developed, which requires huge effort and would benefit from information stored in databases and from automatic retrieval and integration methods. Thus, the systematic collection of pathway information in the form of pathway databases is crucial. Here is reported a succinct list of the most known gene regulatory pathways databases.

- **HRGRN** (Dai *et al.*, 2015): is a graph search-empowered integrative database of Arabidopsis signal transduction, metabolism, and gene regulatory networks. HRGRN employs the highly scalable graph database, Neo4j, to host large-scale of biological interactions among genes, proteins, and small RNAs that were either validated experimentally or predicted computationally. Besides, HRGRN comes with a series of graph path search algorithms to discover unknown relationships among genes and small molecules. HRGRN gives the users the capabilities to build sub-networks based on known interactions. The outcomes are visualized with both rich text, figures and interactive network graphs on web pages. HRGRN is available at <http://plantgm.noble.org/hrgn/>.

- **myGRV** (Bacha *et al.*, 2009): is a database storing information about regulatory links in genetic regulatory pathways. myGRV also allows rapid visualisation of these networks and lets you export network data to a variety of tools. myGRV is available after free registration to use through web browser at the following address <http://www.nottingham.ac.uk/~plzloose/mygm/>.
- **RegNetwork** (Liu *et al.*, 2015): is a data repository of five type transcriptional and post-transcriptional regulatory relationships for human and mouse. RegNetwork aims to develop a platform for collecting the experimentally validated regulations and the predicted regulations. By using RegNetwork, users can query and identify the combinatorial and synergic regulatory relationships among TFs, miRNAs, and genes. As well as providing the statistics of the built regulatory networks by means of queries. RegNetwork is freely available at <http://www.regnetworkweb.org/search.jsp>.
- **TRED** (Zhang, 2008): is an automated pipeline to extract known promoters from databases such as Genbank, EPD and DBTSS, and employ promoter finding program FirstEF combined with mRNA/EST information and cross-species comparisons. Curation has been done to assess computational prediction and ensure data accuracy. As well as, curation has also been provided for transcriptional regulation information, including transcription factor binding motifs and experimental evidence. TRED is available at the follows web address <https://cb.utdallas.edu/cgi-bin/TRED/tred.cgi?process=home>.
- **TRRUST** (version 2) (Han *et al.*, 2015): is a manually curated database of human and mouse transcriptional regulatory networks. The current version of TRRUST contains 8, 908 and 7, 382 TF-target regulatory relationships of 821 human TFs and 859 mouse TFs, respectively. TRRUST database also provides information of mode of regulation (activation or re-pression). Currently 9, 762 (59.9%) of regulatory relationships are known for mode of regulation. TRRUST is available at the following web address <http://www.grnpedia.org/trrust/>. Query results are conveyed in a tabular format and visualized as network by using HumanNet (Lee *et al.*, 2011). HumanNet is a probabilistic functional gene network of 18, 714 validated protein-encoding genes of Homo sapiens. Data can be download in TSV and BioC format respectively.

Table 4 conveys a graphically overview of the features available in each database listed in this section.

Signal Transduction Pathways

All the chemical or physical signals transmitted from a cell to another i.e., a change in conditions between cells is obtained through hormone exchange. As well as, from a cell to the external environment and vice versa, i.e., molecules in food communicate taste and smell through the interaction with specialized sensor cells. This process is known as *signal transduction*, making possible for the cells to interact with the external environment, by detecting molecules outside the plasma membrane and dispatch the information to the inside of the cell. Thanks to continuous advances in experimental research methodologies, it is even clearer that all these chemical or physical signals govern various biological process i.e., control the cell fates, response to blue light and up regulate or down regulate certain genes, form complex signal transduction networks that go under the name of signal transduction pathways. In particular, the proteins responsible for intercepting the stimuli are known as *receptors*, when a *ligand* binding with a receptor, triggers a series of signalling cascade a chain of biochemical events. Signalling pathways interact among them, forming a network allowing to coordinate cellular responses, by combining signalling events among them. Thus, with the term signal transduction pathways, researchers refer to the totality of biochemical mechanisms able to regulate the cellular machinery (Ray, 1999). Signal transduction pathways at

Fig. 3 The adenylyl cyclase signalling pathway, is an example of gene regulation pathway.

the molecular level responses includes changes in the genes transcription or translation tasks, as well as conformational changes in proteins. These molecular events are the core mechanisms controlling cell growth, proliferation, metabolism and many other biological processes. Each component of a signalling transduction pathway is classified according to the role it plays concerning the primary stimulus. An graphical representation of signal transduction pathway is shown in Fig. 3.

A ligand binds to its specific receptor on the cell-surface. As a result, the interaction between ligand and receptor produces a signal that is transferred through a membrane protein-transducer to a membrane-bound effector enzyme. The activity of the effector enzyme produces a small molecule or ion known as the second-messenger. Finally, the second-messenger carries the signal to its ultimate destination which may be in the nucleus, an intracellular compartment, or the cytosol. A few non-polar signal molecules such as estrogens and steroid hormones can spread through the cell membranes and, hence, enter in the cell. Once crossed the membrane, these molecules can bind to proteins that interact with the DNA and modulate gene transcription, altering the gene-expression patterns. A vast diversity of ligands, receptors, and transducers exists, but only a few second-messengers and types of effector enzymes are known. Amplification is an essential feature of signaling pathways. A single ligand receptor complex can interact with some transducer molecules, activating many molecules of effector enzyme. Thus, the production of many second-messenger can activate many kinase molecules that catalyze the phosphorylation of many target proteins. These series of

amplification events is known as a cascade. The cascade mechanism means that small amounts of an extracellular compound can affect large numbers of intracellular enzymes without crossing the plasma membrane or binding to each target protein. There are many types of receptors and various transducers, where bacterial transducers are different than eukaryotic ones. Receptors can be split into two broad classes internal and cell-surface receptors. Internal receptors even known as intracellular, are located in the cytoplasm of the cell, responding to the hydrophobic ligand molecules that can travel across the plasma membrane (Vanderbilt *et al.*, 1987). Once inside the cell, a significant number of these molecules tie to proteins that work as controllers of mRNA synthesis to regulate gene expression. Gene expression is the cell process of transforming DNA into a sequence of amino acids that finally becomes a protein. At the point when the ligand binds to the internal receptor, a conformational change uncovered a DNA-restricting site on the protein. The ligand-receptor complex moves into the nucleus ties to specific regulatory regions of the chromosomal DNA, promoting the start of transcription. Internal receptors can straightforwardly impact the gene expression without passing the signal to different receptors or second messenger. Cell-surface receptors are known as transmembrane receptors (Deller and Jones, 2000; Spear *et al.*, 2000). Transmembrane receptors are located on the cell surface and attached to the membrane, binding to the external specific ligand molecules. These receptors traverse the plasma membrane and perform signal transduction, converting an external cellular signal into an intracellular signal. Ligands that combine with cell-surface receptors don't need to enter into the cell nuclei to influence. A general cell-surface receptor comprises an extracellular ligand-binding domain, a hydrophobic membrane-spanning region, and a domain inside the cell. Cell-surface receptors affect most of the signalling processes in multi-cellular organisms. There are three general categories of cell-surface receptors: ion channel-linked receptors (Ackerman and Clapham, 1997), G-protein-linked receptors (Milligan, 1993; Watson and Arkinstall, 1994), and enzyme-linked receptors (Coussens, 1985). G proteins linked receptors play as transducers transmitting the external stimuli to effector enzymes. G proteins are observed in dozens of signalling pathways including the adenylyl cyclase and the inositol-phospholipid pathways. Ion channel-linked receptors binding a ligand change conformation to open a channel through the membrane that allows specific ions to pass through, i.e., hydrogen, sodium, calcium and so on. Ion channel-linked receptors are observed to act as a second messenger initiating signal transduction cascades and altering the physiology of the responding cell pathway. Finally, the enzyme-linked receptors are cell-surface receptors with intracellular domains associated with an enzyme. When a ligand ties to the extracellular receptor, a signal is conveyed through the membrane activating the enzyme, which starts a chain of events inside the cell that eventually lead to a response. The enzyme-linked receptors operate by a signalling pathway that includes a multifunctional transmembrane protein called a tyrosine kinase receptor. Signal transduction pathways are responsible for the correct cellular function in each tissue and environment (Gumbiner, 1996). Thus a methodology able to structurally represent the signal transduction pathway by using a standard form that can be readily stored, processed, analyzed and visualized by computers would be of great value, as well as visual representation of information make quickly for researcher understand better how signal transduction pathways work.

Signal Transduction Pathways Visualization and Analysis Tools

In this section are summarized some of the most known and used tool in the analysis and visualization of signal transduction pathways. Further information about other tools (not listed in this section) can be found at the follows web address <https://omictools.com/signaling-pathways-category>.

- **Cell Illustrator** (Nagasaki *et al.*, 2010): is a software tool that enables biologists to draw, model, elucidating and simulating complex biological processes and systems. Cell Illustrator allows researchers to model metabolic pathways, signal transduction cascades, gene regulatory pathways and dynamic interactions of various biological entities such as genomic DNA, mRNA and proteins. Cell Illustrator is written by using the Java program language, making it compatible with all the operating system compatible with Java. Cell Illustrator is available for the download at the following web address <http://www.cellillustrator.com/home>. Results can be exported in the CIL, and CSV File format.
- **ChemCell** (Joo *et al.*, 2007): is a particle-based reaction/diffusion simulator designed to model signalling, regulatory, or metabolic networks in biological cells. ChemCell is written in C++ and no additional software is needed to run ChemCell. Furthermore, ChemCell will run on any parallel machine that compiles C++ and supports the MPI message-passing library. ChemCell is an open-source code, and it is freely available for download at <http://www.sandia.gov/~sjplimp/download.html> under the terms of the GNU Public License (GPL).
- **Jarnac** (Sauro, 2000): is an interactive and interpretive language for describing and manipulating cellular system models and can be used to describe metabolic, signal transduction and gene networks, or in any physical system which can be described in terms of a network and associated flows. Jarnac works as a script engine for model building, simulation, and analysis and a simulation engine for SBML files. Performing continuous and stochastic simulations. Jarnac allows users to Export/Import models in SBML XML standard format. Jarnac is currently only supported on Windows and is freely available at <http://sbw.kgi.edu/sbwWiki/sysbio/jarnac>.
- **SBML-SAT** (Zi *et al.*, 2008): is a Systems Biology Markup Language (SBML) based Sensitivity Analysis Tool (SAT). SBML-SAT is designed to run simulation, steady state analysis, robustness analysis, as well as local and global sensitivity analysis for ordinary differential equations (ODE) based biological models. SBML-SAT provides four different global sensitivity analysis methods, including multi-parametric sensitivity analysis, partial rank correlation coefficient analysis, SOBOL's method and weighted average of local sensitivities. SBML-SAT is written by using the Matlab Programming language. Results can be exported in SBML

TENET	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

In the table OSC, Operating System Compatibility indicates in which operating system the tool is supported; FFS, File Format Supported indicates the approved file format for loading/exporting; CSk, Computer Skills refers to the know-how necessary to use the tool; RU, Restriction To Use specifies the scope where is allowed to use the tool; AA Available Applications indicates the types of available tools; V, Visualization specifies the type of support data visualization; finally A, Analysis conveys the type of analysis capability offered by the tool.

Level 1 Version 1 and 2, and SBML Level 2 Versions 1, 2 and 3. SBML-SAT is available for Windows, Mac, and Linux can be freely downloaded from its website <https://www2.hu-berlin.de/biologie/theorybp/?goto=tools>.

- **SimBoolNet** (Zheng *et al.*, 2009): is an software tool for simulating the dynamics of signalling transduction by using boolean networks. Users by specifying a level of stimulation to signal receptors, SimBoolNet simulates the response of downstream molecules and visualizes with animation and records the dynamic changes of the network. SimBoolNet is available as a Java plug-in for Cytoscape, allowing users to take advantage of the functionalities of Cytoscape. SimBoolNet can be freely downloaded from the following website <https://www.ncbi.nlm.nih.gov/CBBresearch/Przytycka/index.cgi#simboolnet>. SimBoolNet import networks encoded by using the delimited text and Microsoft Excel formats. Image files can be saved in the following formats including PNG, JPEG, and vector graphics file formats (including PDF, EPS and SVG, while statistical results can be saved in plain text file format.
- **TENET** (Chua *et al.*, 2015): is a network-based methodology that characterizes known targets in signaling networks by means of topological features. TENET starts computing a set of topological features and then leverages a SVM-based approach to identify predictive topological features that mark known targets. As a result, a computational model is generated and it specifies which topological features are necessary for discriminating the targets and how these elements should be combined to quantify the plausibility of a node being a target. TNET is written in Java feature that makes TNET compatible with Windows, Linux and Mac OSX, and it is freely available to the download at the following web site <https://sites.google.com/site/cosbyntu/software/tenet>.

Table 5 conveys a graphically overview of the features available in each tool listed in this section.

Signal Transduction Pathways Databases

Comprehensive representations of signal transduction pathways have been developed, which requires huge effort and would benefit from information stored in databases and from automatic retrieval and integration methods. Thus, the systematic collection of pathway information in the form of pathway databases is crucial. Here is reported a succinct list of the most known signal transduction pathways databases.

- **NetPath** (Kandasamy *et al.*, 2010): is a manually curated database of signal transduction pathways in humans. NetPath allow users annotation of transcriptionally regulated genes, provides manually curated textual descriptions of each pathway reaction, and data stored in NetPath can be searched by using SPARQL. All pathways stored in NetPath are freely available for download under an adaptive Creative Commons License in BioPAX level 3.0, PSI-MI version 2.5 and SBML version 2.1, Excel, and Tab-delimited formats. NetPath is available at this web site <http://www.netpath.org>.
- **OmniPath** (Türei *et al.*, 2016): is a comprehensive collection of literature curated human signaling pathways. OmniPath main goal is related with the development of an uniform representation of the pathways data, by integrating additional information on the structure and mechanism of the interactions, drug targets, functional annotation. OmniPath aims to provide a ready-to-use web database, as well as an open-source Python module called pypath, which makes pathway analysis easy. OmniPath is freely available at <http://omnipathdb.org>.
- **Reactome** (Croft *et al.*, 2010): is a curated, peer-reviewed resource of human biological processes. Reactome's rationale is to convey the expert consensus view supported by information contained in the literature in a reusable, computationally accessible format. Reactome covers several areas of biology including signaling, immune function, transcriptional regulation,

translation and so on. The Reactome website is reachable at the following web address www.reactome.org. The web site includes a pathway browser and a suite of data analysis tools to support pathway-based analysis of experimental data. Pathways are represented graphically using a Systems Biology Graphical Notation (SBGN)-based representation. Reactome software and data are freely available for download in multiple formats including MySQL, BioPAX, SBML, and PSI-MITAB. Data can also be accessed through the provided Web Services APIs.

- **Signaling Gateway** (Dinasarapu *et al.*, 2011): The UCSD-Nature Signaling Gateway is a comprehensive database of signal transduction pathways. This Gateway represents a collaboration between academia and scientific publishing and is designed to facilitate navigation of the complex world of research into cellular signaling. Signaling Gateway combines expert authored reviews with curated, highly-structured data (e.g., protein interactions) and automatic annotation from publicly available data sources (e.g., UniProt and Genbank). The information and data presented here are freely available to all users. Data can be downloaded in BIOPAX and SBML format. The Signaling Gateway database and related tools are freely available at <http://www.signaling-gateway.org/molecule/>.
- **PANTHER** (Mi *et al.*, 2005): Protein ANALYSIS THrough Evolutionary Relationships is a database of protein families, PANTHER also contains a number of signaling pathways associated with proteins in the database. PANTHER is freely available at the following web address <http://www.pantherdb.org>. PANTHER allows users to download data in SBML and BIOPAX formats.
- **SPIKE** (Paz *et al.*, 2010): Signaling Pathway Integrated Knowledge Engine is a database of highly curated human signaling pathways with an associated interactive software tool. SPIKE interactively graphically displays biological signaling networks, allows dynamic layout and navigation through these networks, and enables the superposition of DNA microarray and other functional genomics data on interaction maps. SPIKE save networks in XGMML format, and allows users to download data in sif and BIOPAX formats. SPIKE is freely available for academic purpose at the following web address <http://www.cs.tau.ac.il/~spike/>.
- **Signalink2** (Fazekas *et al.*, 2013): is an integrated resource to analyze signaling pathway cross-talks, transcription factors, miRNAs and regulatory enzymes. Signalink2 stores data in a MySQL database, where each record in the protein or miRNA tables represents a real protein or miRNA, respectively, and a real entity is represented only by one single record. Proteins could belong to pathways and have topological attributes are represented by means of layers. Allowing users to browse signalling pathways, cross-talks and multi-pathway proteins. Signalink2 data are freely available for download in multiple formats including CSV, BioPAX, SBML, cytoscape, PSI-XML, and PSI-MITAB. Signalink2 is freely available at the following web-site <http://signalink.org>.
- **SIGNOR** (Perfetto *et al.*, 2016): The SIGnaling Network Open Resource (SIGNOR) organizes and stores in a structured format signaling information published in the scientific literature. At the moment of writing, SIGNOR database contains more than 11000 manually-annotated causal relationships between proteins that participate in signal transduction. The entire network can be freely downloaded and used to support logic modeling or to interpret high content datasets. Furthermore, each relationship is connected to the literature reporting the experimental evidence. SIGNOR database is freely available at the follows web address <http://signor.uniroma2.it>. Data can be download in CSV, XLS and casualTAB format.

Table 6 conveys a graphically overview of the features available in each database listed in this section.

Table 6 Signal Transduction Pathways Databases comparison.

Unsupported features are conveyed by black colour, whereas colours convey the supported features for each tool

Name	FFS						O	RU			
	BIOPAX	SBML	SIF	XML	TEXT	Other	HomoSap	Other	AccadOnly	Everyone	AfterRegist
NetPath											
OmniPath											
Reactome											
Signaling Gateway											
PANTHER											
SPIKE											
Signalink2											
SIGNOR											

In the table FFS, File Format Supported indicates the approved file format for loading/exporting; O, Organism refers to the indicates the organism where data come from; RU, Restriction To Use specifies the scope where is allowed to use the tool.

Biological Pathway Data Formats and Standards

Ramakanth C Venkata and Dario Gherzi, University of Nebraska at Omaha, Omaha, NE, United States

© 2019 Elsevier Inc. All rights reserved.

Introduction

The rapid increase, over the last two decades, in pathway data availability can be partly attributed to high-throughput technologies that are capable of rapidly generating massive amounts of data. The costs associated with these technologies have decreased dramatically in the post human genome project era, thereby enabling and accelerating their widespread use (Marx, 2013). As a result, the number of resources for pathway data representation has also increased. In 2013, the number of online resources for pathways and molecular interactions was 547 (pathguide.org), compared to 325 in the year 2010.

Inconsistent semantics and lack of standardization for representing data make it difficult to combine these resources, resulting in costly generation of possibly redundant data, complicating data integration, and causing time delays and lost opportunities. Developing and maintaining consensus regarding semantics and methods for data representation helps to minimize duplication of efforts. Therefore, well defined, shared data languages are critical for data integration and for facilitating knowledge sharing.

Developing one universal pathway data standard might not be feasible due to the inherent diversity associated with the data types and their uses in different branches of biology. For example, pathway data can include among other things information about metabolic pathways, gene regulation, protein interactions, signaling, and gene interactions. A universal data standard would need to consider and incorporate semantics and terminologies used to represent the abstractions in all these contexts (Cary *et al.*, 2005).

However, standardization is necessary to improve consistency and data integration. To this end, community-wide efforts have resulted in a few data formats and standards that have become popular, and are associated with widely used pathway resources, such as Reactome, Panther, KEGG, and Pathway Commons. This article offers a short description of some of these formats, highlighting similarities and differences between them.

Data Formats

BioPAX

BioPAX is a language designed to systematize, standardize, and facilitate the process of pathway mapping, and is the work of several groups. BioPAX is focused on the representation of cellular and molecular pathways and networks, and it facilitates the organization, analysis, and visualization of biological networks and their associated pathways (Strömbläck and Lambrix, 2005).

BioPAX offers a controlled vocabulary (an ontology) for representing aspects of biological pathways related to molecules (including small molecules), genes, gene interactions, events and states (e.g., post-translational modifications such as phosphorylation).

To facilitate data exchange, BioPAX uses OWL (Web Ontology Language) (Shi, 2007). The ontology consists of three classes that include: (1) **Pathway**; (2) **Interaction**; and (3) **Gene and PhysicalEntity**. Depending on the context, the classes can be further subdivided. For instance, BioPax makes available interaction subclasses (e.g., **GeneInteraction**, **MolecularInteractions**) to unambiguously represent the relationships or associations among gene or physical entity classes.

BioPAX uses a validator with a predefined set of rules to look for errors and inconsistencies (Rodchenkov *et al.*, 2013), and it enables the user to include cross-references to other databases, as well as to use standard biomedical vocabularies such as Gene Ontology (Ashburner *et al.*, 2000) and Proteomics Standard Initiative (PSI-MI, discussed below). Apart from representing functional and biological information, the ontology classes are also used to represent references to other sources and annotations (Demir *et al.*, 2010).

BioPAX level 3 is the current version of the biological pathway exchange format and is intended to replace older BioPAX levels. Level 3 makes substantial changes to the level 2 format and semantics. It adds elements such as physical entities, gene regulation, and genetic interactions to broaden the scope of the language. These additional elements allow more explicit representation of complex biological processes. For example, a newly included class in Level 3 called "Degradation" supports the representation of degradation or conversion from one form to another of **PhysicalEntity** (e.g., proteins).

BioPAX is supported by many software programs, and can be used for various purposes, including developing new tools. For example, it has been used for the development of classifiers and simulation models (Fanizzi *et al.*, 2008; Haydarlou *et al.*, 2016). BioPAX-enabled open source programs can be modified or customized to add new features. The Java library, Paxtools (Demir *et al.*, 2013), provides a Domain Object Model (DOM) that enables the use of BioPAX data elements by software developers for customized development of tools. It allows the conversion of data objects and pathway models to different data formats (including different BioPAX levels). Paxtools also internally validates these customized models (Demir *et al.*, 2013). The BioPAX validator allows customization of rules to perform quality checks on more than 100 classes. The report of the validation checks is provided in a human readable format (HTML or XML). The validator looks for common syntactic and semantic inconsistencies and assists in automatic correction of some of these errors. It also normalizes the BioPAX models to facilitate data integration (Rodchenkov *et al.*, 2013), by replacing non-standard identifiers with Uniform Resource Identifiers to ensure data consistency.

Further, BioPAX is used for other purposes such as customized ontology development with tools such as Protégé (Musen, 2015), development and maintenance of central pathway data repositories, such as Pathway Commons (Cerami *et al.*, 2011), and visualization of pathway maps in Cytoscape (Shannon *et al.*, 2003).

Proteome Standards Initiative-Molecular Interactions (PSI-MI) XML

PSI-MI XML 1.0 was proposed and developed by the Human Proteome Organization (HUPO) Proteomics Standard Initiative in 2004 as a solution for the inconsistent data representation practices followed by different databases (Orchard *et al.*, 2012). Although the first version focused only on protein interactions, and did not provide support for numerical parameters, these features were incorporated into later versions. It is currently updated and maintained by the Molecular Interaction workgroup of HUPO PSI. Around 65 interaction data resources support the PSI-MI format (see Relevant Website section).

PSI-MI data is also available in MITAB format (Kerrien *et al.*, 2007) (part of the PSI-MI standard), which allows convenient access to interaction data in tabular format, for use with spreadsheet software. The MITAB format represents binary interactions, where each row contains one pair of interactors and additional columns with other relevant aspects of the interaction (Kerrien *et al.*, 2007).

The root element of the molecular interaction format schema of PSI-MI XML 2.5 is **entrySet**, which can in turn contain one or more entry elements. The entry is the core element that describes one or more interactions, along with the related data as a self-contained unit. An entry element consists of: (1) a **source** element, which describes the source or origin of the data present in the entry; (2) an **availabilityList** element, which contains data availability statements (e.g., copyright information); (3) **experimentList**, which describes the type of experiments by which interactions of this entry were determined; (4) **interactorList**, which lists all the interactors that occur in the entry; (5) **interactionList**, which includes all the interactions belonging to the entry; and (6) **attributeList**, a semi-structured container for other data pertaining to the entry, such as attribute name or reference to external, controlled vocabularies (Kerrien *et al.*, 2007). It is important to note that the format accommodates the representation of nucleic acid interactions and other types of interactions, and both binary interactions and complexes can be represented in the PSI-MI XML format.

PSI-MI uses controlled vocabularies for consistency and to avoid ambiguity. The Open Biomedical Ontologies Foundry (OBO) (Smith *et al.*, 2007) maintains PSI-MI's controlled vocabulary with the namespace prefix "MI". The vocabulary is updated regularly to keep up with evolving technologies.

Efforts in the systems biology community have led to the development of several tools that support the PSI-MI format, including XML parsers for incorporating the format in other tools, format converters to covert PSI-MI XML into BioPAX or HTML, and semantic validators to tackle the problem of data consistency. Cytoscape (Shannon *et al.*, 2003) supports the PSI-MI XML format for visualizing molecular interaction data without requiring additional plug-ins. Examples of data providers that use the PSI-MI XML and MITAB formats can be found in the International Molecular Exchange Consortium (IMEx) (Orchard *et al.*, 2012), and the BioGRID interaction data repository (Stark, 2006).

Systems Biology Markup Language (SBML)

SBML was developed with the intent of providing support for the mathematical modeling of biological systems. SBML models describe the behavior of biological entities and the underlying biochemical processes by taking into account their temporal aspects (Hucka *et al.*, 2015). SBML does not attempt to be a universal language. Rather, its goal is to efficiently represent biological models in a machine-readable format that can facilitate their analysis and dissemination, thus mitigating the issue of incompatibility between different software.

The development of SBML is an ongoing process; different editions are termed levels. Although older level models can be converted into more recent levels through translation, the reverse is not always possible. The latest SBML specification is level 3, and it consists of set of core features that can be extended to incorporate additional features through optional packages.

Representing biological models is inherently challenging, as models often need to incorporate molecular features, concentrations, temporal variables, interactions, and context-dependent events. SBML provides ways to represent these aspects of quantitative modeling. Data objects are used to represent each type of component of a model, along with related information. An overview of SBML core model components is provided below:

1. **Function definitions** (user-defined functions).
2. **Unit definitions** (measurement units).
3. **Compartment** (enclosed space where species are located).
4. **Species** (group of entities sharing similar properties).
5. **Parameters** (used to define symbols and their associated values).
6. **Initial assignments** (initial values for model entities).
7. **Rules** (mechanisms to define the values of variables in a model and to determine their dynamic behavior).
8. **Constraints** (statements that define allowed values for quantities).
9. **Reactions** (processes that can alter the quantities of one or more species).
10. **Events** (state changes in the model that can instantaneously alter quantities in a context-dependent fashion).

Annotation of SBML objects should conform to MIRIAM (Minimum Information Required In the Annotation of Models) guidelines (Novère *et al.*, 2005). URIs (Uniform Resource Identifiers) are used to identify external resources and data used for annotating SBML models and elements. SBML uses XML to encode the models, whereas previous levels of the language used UML to represent data objects (Hucka *et al.*, 2010). In terms of model sharing, the European Bioinformatics Institute (EBI) hosts the BioModels Database (Novère, 2006), a repository with an interactive web interface for storing, retrieving, and exchanging SBML models.

Systems Biology Graphical Notation (SBGN)

SBGN is a collaborative community effort to develop a standard graphical notation to assist in the unambiguous representation of biological or biochemical interactions (Novère *et al.*, 2009). The SBGN language is stratified into levels. A level is organized in such a way as to provide a particular set of functionality to address a specific set of tasks. SBGN's graphical notation schema includes a defined controlled vocabulary, but it also allows the user to take advantage of other controlled vocabularies. However, users are required to include the controlled vocabulary term definitions in the text or figure legend.

SBGN consists of three languages that complement each other: (1) process; (2) entity-relationship; and (3) activity flow diagrams. The rationale behind this arrangement is to separate different properties of biological entities, to reduce complexity, and to improve abstraction. A short description of the three languages making SBGN follows below:

- Process Description Diagram is the representation of all molecular or biochemical interactions and processes involving biological entities. This type of diagram also captures information regarding temporal influences on the processes. This diagram includes two types of nodes: one for entities such as proteins and genes (Entity nodes), and the other for processes like associations and reactions (Process nodes) (Moodie *et al.*, 2015).
- Entity-Relationship Diagram describes the influence of entities on each other and thus each entity is only represented once. The edges represent the positive and negative influences and directionality among entities. Unlike process diagrams, entity-relationship diagrams can better capture the details of the state (e.g., active state) of the entities, but they lack the representation of temporal influences on the states (Sorokin *et al.*, 2015).
- Activity Flow Diagrams are similar to the diagrams observed in tertiary literature (e.g., textbooks and handbooks). Contrary to previous versions, in level 1 version 1.2 the activity flow language uses edges to provide information regarding the positive or negative influence among the entities in the pathways (Mi *et al.*, 2015).

KEGG Markup Language (KGML)

KGML is a standard language used for the KEGG databases (Ogata *et al.*, 1999) and is also the default exchange format used to represent KEGG graph objects (Kanehisa *et al.*, 2004). KGML aids in manual and automatic illustrations of biochemical pathways, and it also enables network modeling and supports computational pathway analysis. Manually drawn representations are used for reference pathways, whereas organism specific pathways are computationally derived from reference pathways. Reference pathways are manually drawn using available scientific evidence, and this pathway information is then computationally assigned to other organisms that share the same pathway. KGML files contain graphical objects that are used to represent entities and their associations (e.g., biochemical reactions) in the specific KEGG pathways. The files also include information on orthologs. The KGML pathway element defines graph objects, where the entry element is a node and the reaction or relation elements are edges. The relation elements are the connections between the gene products and are observed in protein networks, whereas the reaction elements are the connections between the biochemical entities as seen in chemical networks. Metabolic pathways are made up of either protein, or chemical, or both kinds of networks, and regulatory pathways mostly involve protein networks.

Other Languages

Other markup languages for biological pathways include BCML (Biological Connection Markup Language), an XML language based on SBGN standards that attempts to dynamically represent signaling pathways (Beltrame *et al.*, 2011). CellML (Beard *et al.*, 2009), another XML markup language, shares many similarities with SBML but differs in its scope and semantics. CellML places more emphasis on the mathematical modeling and simulation of cellular models, compared to SBML.

Closing Remarks

This article has given a brief overview of a few widely used languages for representing biological pathways, and it is by no means a comprehensive list of all standards and formats that have been developed over the years. The choice of a particular language is dependent on the problem at hand, as specific languages are better suited to particular domains than others. For example, PSI-MI is the language of choice for representing protein-protein interactions, whereas SBML is specifically designed to allow the unambiguous representation of mathematical models.

Biographical Sketch

Ramakanth Chirravuri Venkata, Pharm.D. Ramakanth Chirravuri Venkata is currently a Biomedical Informatics Master's student at the University of Nebraska at Omaha. He completed his Doctor of Pharmacy degree from Osmania University, India in 2015. His research interests include computational cancer biology, cancer pharmacology and therapeutics.

Dario Ghersi, M.D., PhD Dario Ghersi received his M.D. in 2004 from the University of Genoa, Italy, with a thesis on a mathematical model of the immune system. He then pursued a PhD in Computational Biology at Mount Sinai/New York University. From 2010 to 2014 he trained as a Postdoctoral Fellow at Princeton University, developing network-based and structural approaches to probe protein function. In 2011, he was awarded an American-Italian Cancer Foundation fellowship to develop computational methods for the analysis of cancer mutations. He is currently on the faculty of the School of Interdisciplinary Informatics at the University of Nebraska at Omaha. His research interests focus on cancer informatics, immunoinformatics, network biology, and structural bioinformatics.

Biological Pathway Analysis

Ramakanth Chirravuri Venkata and Dario Gherzi, University of Nebraska at Omaha, Omaha, NE, United States

Introduction

Biological pathways can be defined as a set of interactions between biomolecules associated with well-defined cellular changes. Biological pathways are involved in signaling, metabolism, gene expression, and other critical biological processes. Over the years, the systems biology community has made an effort to curate biological pathways using machine readable mark-up languages to improve information exchange, algorithm development, and reusability.

Pathways can be represented using the network formalism, as directed or undirected graphs. Representing pathways as networks is beneficial, as we can take advantage of the many graph-based approaches for data mining, which can extract network features with important biological correlates (Pavlopoulos *et al.*, 2011; You *et al.*, 2006). For example, readily available softwares for network visualization and analysis like Cytoscape (Shannon *et al.*, 2003), Gephi (Bastian *et al.*, 2009), as well as libraries like igraph (Csardi and Nepusz, 2006) can calculate basic network properties including degree centrality (number of edges of a node), betweenness centrality (number of all shortest paths going through a node, used to identify "bottlenecks" in a network), clustering coefficient (which measures the potential of a network to be divided into clusters), network motifs (recurrent patterns in a network), and other measures that are not only interesting from a graph-theoretical perspective but correlate with biological features.

The importance of network-based approaches for pathway analysis is also evident in the way biological pathways are stored. To the more traditional relational model the systems biology community has added graph databases, which allow the visualization, integration, and analysis of heterogeneous data corresponding to different data formats and types (Lysenko *et al.*, 2016). For example, the Neo4j powered graph databases offers support for querying complex disease maps (Yoon *et al.*, 2017).

Specific approaches to analyze biological pathways are discussed below.

Graph Mining Approaches

Graph pattern mining is a broad concept, wherein different measures (known as *interestingness* measures) or functions are considered for different analyses. Several algorithms are available for identifying recurring graph patterns, and for finding significant and discriminative features in the graphs. An important concern associated with graph mining is the combinatorial complexity of the algorithms and the related scalability issues (Cheng *et al.*, 2014).

An important task in biological pathway graph mining is the identification of densely connected subgraphs that are sparsely connected to rest of the network. Density measures such as edge density (average degree) or edge ratio can be used to identify dense sub-graphs. Choice of the algorithms is based on whether the graph is directed or undirected. If the graph is undirected, traditional algorithms such as Greedy or Goldberg (Charikar, 2000; Goldberg, 1984) may be suitable. For directed graphs, maximum-flow based algorithms have been used successfully in the past (Balalau *et al.*, 2015; Khuller and Saha, 2009).

Mining algorithms are formally classified as *a priori* based approaches and *pattern growth* approaches. *A priori* based approaches generally use a breadth-first strategy to identify frequent substructures. In contrast, pattern growth approaches recursively grow a frequent subgraph, using a depth-first exploration strategy, or a combination of depth first search and breadth-first search strategies (Kavitha *et al.*, 2011).

Clustering techniques (hierarchical, partitioning, or random walk based) are used to reduce the complexity of the networks, by grouping similar entities together. The clusters can be visualized with a variety of tools, such as Arena3D (Harel and Koren, 2001; Pavlopoulos *et al.*, 2008). However, if the clusters within the graph are uniform, the clusters produced by clustering algorithms may be arbitrary. For this reason, visual inspection of graphs for patterns and clusters is imperative (Schaeffer, 2007).

Classification of features can be done using either kernel based (e.g., Support Vector Machines) or graph embedding methods. Graph kernels can be used to analyze structural patterns and classification problems. Graph kernels use matrix algebra operations to allow linear representation of the data (Nabhan, 2014). Graph embedding methods are routinely employed to reduce dimensionality of the data, and to facilitate further analysis and representation. Commonly used graph embedding methods are Principal Component Analysis (PCA), which takes into account data variance, and Linear Discriminant Analysis (LDA). Compared to PCA, LDA can achieve better class separation, but it can be severely affected by outliers (Yan *et al.*, 2007). Newer techniques use combinations of two or more of the methods mentioned above (e.g., kernel PCA) (Schölkopf *et al.*, 1997).

Many types of graph mining algorithms are available, with no single algorithm being suitable for all domains. Before selecting an appropriate method for graph mining, we need to be mindful of some of the distinguishing features of biological data: (1) graphs in the biological domain tend to be much larger than graphs observed in other domains; (2) the directionality of the edges is important as it conveys vital information about associations among entities (Aggarwal and Wang, 2010); and (3) heterogeneity and dynamic/temporal features of biological data may complicate data integration (Ozsoyoglu *et al.*, 2006).

Pathway Alignment Approaches

Pathway/network alignment is analogous to sequence alignment, where the goal is to identify similar or conserved regions across different species. The rationale behind identifying conserved regions is that it can be used to uncover functional similarities across species. Traditionally, only protein-protein networks were used for network alignment, but due to the emergence of high-throughput technologies in other domains, most biological networks are now used for alignment and comparison (Bayati *et al.*, 2013).

Pathway alignment approaches focus on the topological similarities that exist between networks and that may provide valuable information on biological function. Network alignment can also complement sequence alignment in identifying orthologs (Singh *et al.*, 2008). As in the case of sequence alignment, network alignment can be global or local. Although global alignment approaches are useful in identifying conserved large subgraphs, they may fail to identify localized network regions that are topologically similar.

In addition, network alignment approaches can be classified as pairwise or multiple, based on the number of networks being compared. Pairwise alignment involves alignment and comparison between two networks, whereas multiple alignments involve more than two networks. These alignments can be further sub-classified based on the type of node mapping in the networks being compared (one-to-one, one-to-many and many-to-many) (Clark and Kalita, 2014; Faisal *et al.*, 2015).

Comparisons across networks can also be performed without alignment, by quantifying their topological properties (e.g., degree distribution). However, this quantification is not suitable for identifying conserved regions across networks (Faisal *et al.*, 2015).

Local Alignment Approaches

Table 1 shows a range of local pairwise and multiple aligners. Local aligners aim to align only part of a network, with some methods handling only pairwise alignment and others returning multiple alignments as well. NetworkBlast (Kalaev *et al.*, 2008) is an extension of an older local aligner called PathBlast, that uses a probabilistic model for comparing multiple alignments (Tian and Samatova, 2009). NetAligner is a web server to align and compare complexes, pathways, or interactomes against interactomes (Pache *et al.*, 2012). MaWISH (Koyutürk *et al.*, 2006) uses a scoring function based on evolutionary models to compare networks. AlignMCL (Mina and Guzzi, 2012) uses Markov models to identify functional modules in the aligned graphs (Meng *et al.*, 2016).

The performance of local alignment approaches can be assessed by quality measures such as semantic similarity score, sensitivity/specificity, and F-score (Faisal *et al.*, 2015).

Global Alignment Approaches

Global network aligners use different strategies and approaches to align and compare networks. In brief, traditional aligners examine the topological similarities using a two step approach involving: (1) the use of a node cost function to identify pairwise node similarities; and (2) an alignment strategy to yield an optimal alignment across networks. Some of the global aligners also consider sequence similarities between the node pairs (e.g., proteins) alongside topological similarities (Meng *et al.*, 2016). Contrary to mapping approaches used by local aligners, global pairwise aligners use one-to-one mapping approach, and global multiple aligners use many-to-many mapping approach, to identify large common regions among the networks being compared. Similar to local alignment, quality measures are used to assess the alignment quality but instead of using only biological measures, topological quality measures are also considered (Crawford *et al.*, 2015; Faisal *et al.*, 2015).

Quality Measures for Global Alignment Methods

Topological quality measures such as node correctness, symmetric substructure score, largest connected common subgraph and number of aligned clusters are employed to assess true node mapping and edge conservation (Faisal *et al.*, 2015; Milano *et al.*, 2017).

Table 1 Local network alignment approaches

Name	Strategy
Pairwise aligners	
NetAligner	Monte Carlo permutation test to assess significance
NetworkBLAST	Combination of a greedy method with dynamic programming
MaWISH	Alignment scoring based on edge weights and cost-function
AlignMCL	Markov clustering algorithm for mining
Multiple aligners	
Graemlin	Progressive alignment
NetworkBLAST-M	Layered alignment

Biological quality measures such as exact protein ratio, normalized mean entropy, exact cluster ratio, Gene Ontology (GO) enrichment and GO semantic similarity are used to evaluate the functional similarities among aligned node pairs and functional consistency in the alignments (Faisal *et al.*, 2015; Panni and Rombo, 2013).

Pathway Analysis in Genome-Wide Association Studies

Genome Wide Association Studies (GWAS) use statistical models to investigate the association between variants (Single Nucleotide Polymorphisms) and phenotypes. Despite the debate regarding statistical significance vs. biological relevance in the scientific community, GWAS have been an important source for generating novel hypotheses in the field of genetics. GWAS tend to be suitable for detecting common variants associated with specific phenotypes (Teslovich *et al.*, 2010; Visscher *et al.*, 2012). However, in the case of complex diseases associating individual variants to specific phenotype can be challenging due to their small effect sizes. Another considerable issue with GWAS is that they use stringent p-value thresholds that are corrected for multiple hypothesis testing, in order to control false positives. This threshold may occasionally get rid of moderately significant genes that may represent biologically plausible candidates for genotype-phenotype associations (Jia *et al.*, 2011).

Pathway analysis may substantially alleviate these problems by examining the combined effects of related single variants, and also by aiding in the identification of related novel variants that are associated with the phenotypes. Pathway analysis examines association with the phenotype of interest using gene sets instead of individual genes (Kao *et al.*, 2016; Zhong *et al.*, 2010). Pathway analysis of GWAS studies generally consists of three steps: (1) determination of gene sets suitable for pathway analysis (e.g., Gene Ontology (Ashburner *et al.*, 2000) or KEGG (Ogata *et al.*, 1999)); (2) mapping variants to their respective genes; and (3) using statistical models to examine associations.

Conclusions

As it is the case for most bioinformatics approaches, biological pathway analysis has benefited from major advancements in high-throughput technologies and increased availability of data. Combined with advancements in computer hardware, high-performance computing, and algorithms in the fields of graph theory and machine learning, biological pathway analysis can now be used to assist in hypothesis generation, to summarize the results of large high-throughput experiments, and to computationally validate existing hypotheses.

Biographical Sketch

Ramakanth Chirravuri Venkata, PharmD, is currently a Biomedical Informatics Master's student at the University of Nebraska at Omaha. He completed his Doctor of Pharmacy degree from Osmania University, India in 2015. His research interests include computational cancer biology, cancer pharmacology and therapeutics.

Dario Gheri, MD, PhD, received his MD in 2004 from the University of Genoa, Italy, with a thesis on a mathematical model of the immune system. He then pursued a PhD in Computational Biology at Mount Sinai/New York University. From 2010–2014 he trained as a Postdoctoral Fellow at Princeton University, developing network-based and structural approaches to probe protein function. In 2011, he was awarded an American-Italian Cancer Foundation fellowship to develop computational methods for the analysis of cancer mutations. He is currently on the faculty of the School of Interdisciplinary Informatics at the University of Nebraska at Omaha. His research interests focus on cancer informatics, immunoinformatics, network biology, and structural bioinformatics.

Two Decades of Biological Pathway Databases: Results and Challenges

Introduction

Biomolecular pathway databases are essential components of bioinformatics workflows, and are integral to understanding disease and health processes. Pathways are usually defined as sets of biomolecules that cooperatively accomplish a specific cellular outcome. They have been defined at different levels of organization, for example, gene sets ([Liberzon et al., 2015](#)), networks of process-specific interactions ([Glaab et al., 2012](#); [Fazekas et al., 2013](#); [Rahmati et al., 2017](#)), or detailed kinetics of molecular events that cause a specific phenotype ([Kanehisa, 2000](#); [Nishimura, 2001](#); [Fabregat et al., 2016](#)). However, the underlying concept across all of these definitions is functional dependency of a set of biomolecules (including proteins) through molecular networks.

Description of these networks is usually defined across different papers, which focus on network components, dynamics, or diverse phenotype-specific differences. They are collected by data curators, organized in pathway maps by experts, and stored in online databases.

Although concept of a pathway as a set of proteins that co-function to accomplish a task (or result in a phenotype) has been around since early 1950s ([Komai, 1950](#); [Barratt et al., 1954](#)), their first formal representation in a knowledge base, EcoCyc (a branch of the current BioCyc group), was introduced in 1993 ([Karp and Paley, 1994](#)). It did not take long for researchers to recognize the significance of these databases in molecular biology research. On December 1, 1995, KEGG ([Kanehisa, 1997](#)) released its first version, Release 0.1, which contained gene classification tables. The first official version (Release 1.0) was introduced on October 24, 1996, and covered five organisms. By incorporating molecular interactions into metabolic gene sets, KEGG introduced the first web hosted pathway diagrams. In July 1997, it added signal transduction and gene regulatory pathways to its metabolic pathways, encompassing the three major categories of pathways for the first time ([Kanehisa, 1997](#)).

Pathway databases and analysis tools are valuable during gene set annotation, especially the sets, which are obtained from high-throughput (HTP) studies. Predominantly, the goal is to understand which genes play the most central, functionally important role in a specific phenotype such as a disease state or response to a drug.

Over the past two decades, the need for comprehensive and accurate pathway maps has resulted in creation of multiple broad and specific pathway databases. We review accomplishments and highlight remaining challenges.

Pathways in Systems Biology

Pathways are essential models in systems biology research and personalized medicine. High-dimensional data generated by HTP platforms, such as gene and protein arrays, sequencing, and ChIP-seq technologies, make integrating and understanding the information hidden in the HTP data challenging. Almost all HTP data analysis workflows use pathway and functional annotation and analysis to aid data interpretation and hypothesis generation.

Since almost every process or event in living organisms is a result of collaboration of one or more proteins, it is advantageous to summarize complex HTP data as less convoluted sets of complexes and signaling cascades. Pathways provide the information necessary to find and interpret these sets by grouping proteins whose coactivity is known to be important in cellular events or phenotypes. One common application of HTP technologies is in understanding the differential effect of treatments or diseases on genes, proteins, and metabolites. Pathway analysis of this data helps to fathom the underlying mechanisms of cells that are relevant to those conditions. Understanding the relevance of genotype and phenotype ([Carter et al., 2013](#)), differentiating subtypes of diseases ([Chuang et al., 2007](#)), and developing targeted-therapies ([Yauch and Settleman, 2012](#)) are a few examples of topics in which pathway analysis plays a significant role in current molecular biology and personalized medicine research.

Pathway Databases

As of August 2017, over five hundred pathway annotation, analysis, and visualization portals and tools are listed at [pathguide.org](#) portal ([Bader et al., 2006](#)). We review the most frequently used resources by considering different aspects such as data access, proteome coverage, level of domain-specificity, level of annotation provided, analytic services offered, format of input and output supported, etc. [Table 1](#) summarizes features of the most widely used databases of different pathway groups. We restrict the scope of this review to databases that are fully publicly available and include pathways for human. KEGG and BioCarta are the only two exceptions to these criteria, as KEGG was in the public domain until 2011, and BioCarta became free after its first few years as a commercial product.

Table 1 A list of major pathway databases and their features

Pathway Database	Status	First Release Listed/ Publication	Latest Release ^a (date/version)	Number of Annotated Genes/proteins (Unique)	Resource type	Level of Domain Specificity ^b	Services	Data Accessibility	File formats	Link	Reference

Fig. 1 (A) Timeline of development and update of major pathway databases grouped based on sources of their data: curated, integrated, hybrid, and predicted. (B) Comparison of human protein-coding gene coverage across different publicly available pathway databases. Starting from Reactome as the largest primary pathway database, this diagram shows incremental coverage for genes after adding individual databases. We have sorted primary and hybrid databases by the number of genes that each one adds. Approximating size of human genome to 20,000 genes, 27% of genome is annotated only through predictions (extended pathways) and 10% of genome remains void of pathway annotations.

Pathway Annotation Classes Based on Their Data Source

Pathway databases can be clustered into five major classes: primary, integrated, hybrid, extended, and *de novo*. They each offer different types of data, and they vary in proteome coverage and the detail they provide. Primary databases were the first category of pathway databases to be developed. Next, integrated and hybrid databases, which are the results of integration of primary pathway databases, appeared. Finally, extended pathway databases were developed to increase coverage and reduce bias present in the other three categories of databases. **Fig. 1(A)** depicts the timeline of development and update of the main representatives of the first four classes of pathway databases.

Primary pathway databases

Primary pathway databases, such as KEGG (Kanehisa, 1997), STKE (Gough, 2002), BioCarta (Nishimura, 2001), and Reactome (Fabregat *et al.*, 2016), were originally developed by expert collection of experimental findings that were spread across published papers. Biologists usually consider these databases to provide the highest quality pathway data. However, the drawbacks of primary databases include slow growth, partly due to limitations in technologies for experimental pathway discovery, and partly due to their reliance on manual human expert curation, which results in their limited proteome coverage.

To improve the speed and comprehensiveness of pathway curation, automatic literature mining tools have been developed (Kemper *et al.*, 2010; Ravikumar *et al.*, 2014a,b). However, these tools have several limitations and challenges such as the trade-off between the level of detail in their output and the complexity of their design, and the need for education of users to teach them how to define parameters, such as confidence level, to customize searches. Longer and more detailed lists of such challenges are reviewed in Ravikumar *et al.* (2014a,b); Huang and Lu (2016). Moreover, challenges for primary pathway databases include data heterogeneity and diversity in the nomenclature used, both of which will be further discussed in the following sections.

Integrated and hybrid pathway databases

Integrated pathway databases were developed by combining data from multiple primary databases into one consolidated database. Examples include Panther (Mi *et al.*, 2016), PathwayCommons (Cerami *et al.*, 2011), ConsensusPathDB (Herwig *et al.*, 2016), and PathCards (Belinky *et al.*, 2015). While they provide significantly increased coverage compared to primary databases, the challenge is the heterogeneity of the consolidated data, since each primary database may provide a different quality of curated information and level of detail.

The third class of pathway databases, which were developed along with integrated pathway databases, is *hybrid* databases (Liberzon *et al.*, 2015). They combine data from primary databases with new data curated from papers. Examples of these databases include PID (Schaefer *et al.*, 2009), iPavs (Sreenivasiah *et al.*, 2012), and WikiPathways (Kutmon *et al.*, 2016). Similarly to integrated databases, coverage is increased, but the information provided may be of inconsistent quality.

Data integration improved the proteome coverage of the primary databases, and quickly became popular among bioinformaticians and systems biology data analysts. However, integrated pathway databases still do not annotate a large portion of human protein-coding genes, limiting analysis and interpretation of HTP data. It has been shown that the twenty major pathway databases, combined, cover less than 65% of the human genome, leaving the rest of the genes as so called “pathway orphans” (Rahmati *et al.*, 2017).

Furthermore, integrating pathway data and keeping it up-to-date is a non-trivial task due to several challenges such as ID heterogeneity, ambiguous gene naming, open vocabulary, and lack of standard protocols for paper curation. Details about these challenges will be discussed in the following sections.

Extended pathway databases

Discovering and annotating pathways using experimental methods is expensive and time consuming, and may provide limited or biased coverage. In order to facilitate comprehensive and effective discovery of functional dependencies, several groups have suggested computational methods to integrate different types of biological data, such as sequence, expression, and interaction networks to predict novel protein-pathway associations.

Comparative genome analyses (Osterman and Overbeek, 2003; Moriya *et al.*, 2007; Port *et al.*, 2013), genome mapping (Date and Marcotte, 2003), and network integration (Glaab *et al.*, 2010, 2012; Herwig *et al.*, 2016; Rahmati *et al.*, 2017) are some of the methods that have been successfully applied to predict functional dependencies of proteins, and assign them to pathways. While the first two categories of methods are effective in capturing conserved functions of proteins, the advantage of network integration methods includes the capability of predicting organism-specific protein functions.

ConsensusPathDB (Herwig *et al.*, 2016), EnrichNet (Glaab *et al.*, 2012), PathDIP (Rahmati *et al.*, 2017), and PathExpand (Glaab *et al.*, 2010) are four major pathway data portals that integrate physical protein interactions with literature-based pathway information, to predict novel functional dependencies among proteins and pathways. Major differences among these databases, beyond the background data that they use, include the prediction algorithms used and the services provided.

ConsensusPathDB integrates a comprehensive list of pathways from twelve source databases. It can perform pathway enrichment analysis and gene annotation with pathways. However, it does not provide pathway annotation for genes that are not covered by its twelve pathway sources. It also performs neighborhood-based entity set (NEST) searches to predict gene sets that are closely related to the query list.

In EnrichNet, users first enter a list of query genes, and select a protein-protein interaction (PPI) network on which to base the analysis – either choosing from a list of four PPI networks provided by developers, or using the user's PPI network – and then customize their analysis by selecting an annotation database from the eight available databases, five of which are pathway databases. The analysis can be made condition-specific by choosing a gene expression dataset to be integrated with the selected PPI network. Although EnrichNet provides novel predicted protein-pathway associations for protein groups through a random walk between the target list and pathways, it cannot provide annotations for single proteins (the query list must contain at least ten identifiers) (Glaab *et al.*, 2012).

PathExpand has used three pathway databases, Biocarta, KEGG, and Reactome to provide proteins that act as pathway seeds on the PPI network. For its background network, it combines data from five publicly available PPI databases. Next, it defines three criteria for the relative connection of each protein in the PPI network to each pathway, in order to associate each protein to the seed pathway. Users can customize their search by selecting one of 1859 pathways provided by PathExpand and setting up expansion parameters. While its output includes known and predicted pathway members and their interactions as a gene list, an interactive graph layout, and a Cytoscape readable network, PathExpand does not support gene annotation or pathway enrichment analysis.

PathDIP integrates physical PPIs and known pathways from twenty primary and hybrid pathway databases to calculate a physical dependency score (association score) for proteins and pathways. Users can customize their search and analysis by choosing any subset of the twenty pathway databases. They can also decide on the type of protein-pathway association sets to include, i.e., *core* (curated) or *extended* (curated and predicted). Importantly, annotations for each gene are independent of the full input list. PathDIP also provides pathway and term over-representation analysis services. Results are available in different views, for example, table, matrix, or text files with word frequencies from enriched pathway titles.

Although extended pathway databases improve data coverage and decrease data biases (Fig. 1(B)), they cannot fully resolve these issues. Extended databases combine different types of biological data to extract hidden information in them. However, they are prone to incompleteness and noise derived from their sources, which results in presence of false positives and false negatives in their predictions (Rahmati *et al.*, 2017).

De novo pathway discovery

The last group of pathway databases includes *de novo* pathway prediction tools. *De novo* pathway discovery methods typically use a background network, and hypothesize that tightly connected gene or protein subnetworks are functionally related. The background network can be global, such as a full PPI network (Oliver, 2000; Sun *et al.*, 2012), or it can be constructed from condition-specific data such as from gene expression or genome-wide association studies (Chuang *et al.*, 2007; Brorsson *et al.*, 2009; Hung *et al.*, 2010; Jia *et al.*, 2011; Alcaraz *et al.*, 2017; Zhang and Zhang, 2017). Since these methods are not limited to prior knowledge about protein functions, they can discover novel pathways. Considering the availability and rapid growth of HTP biological data,

these methods are essential to annotate less-studied proteins and functions, which may be conserved across different conditions, or may be specific to a certain condition.

However, this category of pathway detection methods is not free of disadvantages. One of the biggest challenges is evaluating the quality of the discovered pathways. One approach to evaluating the discovered pathways is to use known data available in primary, integrated, and extended pathway databases. However, using previous studies to evaluate novel pathways can lead to biased conclusions, due to overestimation of the quality of results for the known data, while underestimating the quality of predictions that discover novel pathways. In order to address this problem, *Batra et al.* have suggested a framework for creating artificial networks and pathways (*Batra et al., 2017*). They have compared the performance of seven publicly available *de novo* pathway discovery software and applications, and concluded that none of them is consistently superior to other ones. Therefore, they have suggested guidelines on how to select a method that fits a specific study. Their comparison method is the first attempt to quantitatively compare *de novo* pathway evaluation methods (*Batra et al., 2017*).

Domain-Specificity of Pathways

The level of domain-specificity is another factor based on which we can categorize pathway databases. While some pathway databases focus on very specific classes of signaling cascades, such as autophagy (*Xie and Klionsky, 2007*), or apoptosis (*Doctor et al., 2003*), other databases cover broader areas, such as signal transduction (*Kandasamy et al., 2010; Gao et al., 2013*), metabolism (*Romero et al., 2005; Ma et al., 2007; Glaab et al., 2012; Wishart et al., 2013*), gene regulation (*Han et al., 2015; Marbach et al., 2016*), tissue and disease signaling (*Huang et al., 2008; Schaefer et al., 2009; Simão et al., 2010*), or drug response pathways (*Whirl-Carrillo et al., 2012*); or provide even more general and comprehensive information about pathways, such as KEGG, Reactome, WikiPathways, or PathDIP (*Kutmon, et al., 2016*).

Level of Pathway Details

Pathway databases also provide varying levels of molecular detail and annotation. Some of them, such as MSigDB (*Liberzon et al., 2015*), and ConsensusPathDB (*Herwig et al., 2016*), only include gene sets. Other databases such as PhosphositePlus (*Hornbeck et al., 2015*) and SIGNOR (*Perfetto et al., 2016*) provide process-specific interaction networks, while SPIKE, WikiPathways, Reactome and KEGG (*Paz et al., 2011; Kutmon, et al., 2016; Fabregat et al., 2016; Kanehisa et al., 2016*) describe details about the dynamics of interactions, including the sequence of events and detailed reactions (*Fig. 2*).

Databases of gene sets (*Fig. 2(A)*) and process-specific interaction networks (*Fig. 2(B)*) are sufficient for pathway and network enrichment analyses. However, databases that provide details about the dynamics of pathways are required for analyses that aim to model and interpret the sequence of reactions and events that comprise a biological process (*Fig. 2(C)*).

Design, Services, and Data Sharing

Pathway databases containing process-specific interaction networks usually provide pathway enrichment and network analysis services. Their data and analysis results can be stored and downloaded as text in a variety of simple file formats such as GMX (Gene Matrix format), GMT (Gene Matrix Transposed format), and PSI-MITAB (Proteomics Standards Initiative – Molecular Interactions). Some of the database portals provide visualization tools (e.g., EnrichNet, ConsensusPathDB), such as bar-plots, word-clouds, or networks (*Glaab et al., 2012; Herwig et al., 2016*).

However, these file formats and visualization tools are not detailed enough to represent the integrated dynamic reactions that form pathways. For example, they do not support ordering of events, or hierarchies of reactions and pathways. This type of data needs to be represented as diagrams in rich, machine-readable file formats such as BioPAX (Biological Pathways Exchange), SBML (Systems Biology Markup Language), and SBGN (Systems Biology Graphical Notation). Understanding the contents of these files usually requires special parsers, such as Paxtools (*Demir et al., 2013*). Some of these databases also provide visual diagrams of pathways in PDF, or image file formats. Databases such as Reactome (*Fabregat et al., 2016*), SPIKE (*Paz et al., 2011*), and ACSN (Atlas for Cancer Signaling Networks) (*Kuperstein et al., 2015*) offer interactive pathway maps through which users can zoom in and out, select a particular part of map to see more details, and hide/show specific types of molecules or reactions.

Reactome and WikiPathways make available data and services at different levels of detail, and in several different formats. For example, Reactome not only provides pathway data, but also offers services such as enrichment and network analysis. Its data and search results can be downloaded as gene sets in GMT, interaction sets as MITAB, and full dynamic pathways in BioPAX, SBML, and SBGN formats. The full Reactome database is also provided as a textbook in PDF and RTF formats. Similarly, WikiPathways provides gene sets in TXT, dynamic pathways in BioPAX, and diagrams in SVG, PDF, and PNG formats. Therefore, familiarity with pathway data sharing protocols and different types of pathway data representation can be useful when selecting the download format when using their data and services.

Data accessibility and pathway data sharing are other factors that distinguish individual databases. While many pathway databases support easy download of their full data (*Kutmon, et al., 2016; Fabregat et al., 2016; Herwig et al., 2016*), others restrict users' access at different levels; some only provide restricted download, for example, HPCIN and KEGG (*Huang et al., 2008; Kanehisa et al., 2016*). A few publicly available databases, such as PathCards (*Belinky et al., 2015*), let users browse the database

Fig. 2 Three major groups of pathway definitions based on level of detail. (A) *Gene sets*: genes grouped based on their functions. Usually used for over-representation and enrichment analysis, or for extracting functional gene annotations. (B) *Process-specific interaction networks*: genes inside each pathway are connected through functional links, providing high level molecular network topology. (C) *Dynamics in pathways*: Details about order of events, type of signaling, small molecules necessary to facilitate reactions, types of reactions, etc. are included in pathway maps and represented as images, interactive maps, or rich xml-based file formats (An example from Reactome (R-HSA-157858: Gap junction trafficking and regulation)).

but do not allow download. The last group, which are out of scope of this review, are fully commercial databases for which users need to purchase a license. Examples include Ingenuity Pathway Analysis (see Relevant Websites section), Tocris Bioscience Signaling Pathways (see Relevant Websites section), and Sino Biologicals (see Relevant Websites section).

Platforms for Pathway Reconstruction

In order to facilitate the design and development of pathway descriptions, several biomolecular reaction and pathway editors have been developed (Table 2). CellDesigner (Funahashi *et al.*, 2008), PathVisio (Kutmon *et al.*, 2015), and PathwayMapper (Bahceci *et al.*, 2017) are three widely used, publicly available tools, while Cell Illustrator and PathwayBuilder are two commercial products for designing and editing pathways. Payao (Matsuoka *et al.*, 2010) is a platform that uses CellDesigner to provide an online editor specific to pathway model curation, exchanging comments, and recording the discussions among collaborators.

Challenges

Pathways are models used by humans to describe, share, and discuss knowledge about cellular events. High demand for these models has resulted in the development of many pathway databases and analysis services. Despite all the efforts and achievements in pathway databases in the last twenty-four years, many challenges remain. While our incomplete knowledge of cellular processes is one major issue, lack of consensus on definitions, curation and annotation protocols, structured vocabulary, and context of pathways, limits the utility of all available information.

Human Proteome Coverage

Currently, Reactome (V60) and KEGG (release 81), the two largest primary pathway databases, annotate 10,347 and 6886 unique protein-coding genes, respectively. Despite their size, they only overlap by 53%, and thus cover only about half of the human proteins, leaving over 9000 proteins with no pathway annotation (Rahmati *et al.*, 2017). Incompleteness of proteome coverage results in several challenges. First, any enrichment analysis using any one of the largest single primary database may not consider ~50% of the input proteins. Second, due to the small overlap of the primary databases, using different databases for enrichment analysis will provide inconsistent results. Although development of integrated databases has considerably reduced both problems, it has been shown that about 37% of the human protein-coding genes still lack pathway annotation, even after the 20 largest and most widely used pathway databases were integrated (Rahmati *et al.*, 2017).

Extended pathway databases were developed to provide improved proteome coverage. For example, pathDIP (version 3) makes available pathway annotation for over 90% of human protein-coding genes, 12,630 genes covered by integrated primary databases and 5400 additional genes covered by predicted pathway associations. While extended databases provide evidence for the physical association of proteins with pathway literature-based members, they still leave about 10% of protein coding genes devoid of annotations, mainly due to incompleteness and bias in their resources. Importantly, due to the integration of diverse resources, level of detail and quality of protein annotation is highly dependent on the quality of data available in those sources.

ID Conversion and Naming

An overarching challenge in pathway data integration is the diversity of the type and version of IDs, and ambiguity in the gene symbols used by different databases. For example, while SIGNOR accepts official gene symbols and UniProt IDs, it does not support Entrez Gene IDs; in contrast, SPIKE supports gene symbols and Entrez Gene IDs, but not UniProt IDs. While many major pathway and general bioinformatics resources have built-in ID conversion tables, and allow users to input different ID types, converting IDs is not trivial since most of the IDs are not fully stable, and some conversions are one-to-many. It can cause ambiguity (and imprecision) when using less frequently updated databases, and when curating older papers. This problem is particularly noticeable when using databases that are no longer updated such as BioCarta, SPIKE, INOH (Yamamoto *et al.*, 2011), and STKE.

Ambiguity in gene symbols (and their synonyms) is an even more challenging problem, as gene symbols are not unique identifiers. For example, PKB is a synonym for both AKT1 and PTK2B, and MCP-1 refers to both Metaphase Chromosome Protein and Monocyte Chemo attractant Protein 1. This can cause errors and inconsistency in curating papers, and in study results.

Although initiatives such as HGNC (Gray *et al.*, 2015) approach this problem by maintaining up-to-date ID-conversion tables and lists of gene names, the problem remains for other reasons, such as software errors in reading and representing gene names.

Ziemann *et al.* have systematically scanned 35,174 supplemental excel files attached to 3597 papers published between 2005 and 2015 in eighteen high-impact journals (Ziemann *et al.*, 2016). Based on their estimates, almost one fifth of the gene names in papers and their supplemental material are erroneous due to MS EXCEL converting gene names to dates and floating-point numbers. Therefore, structured curation, proper data sharing workflows, and support for data provenance, are essential to reduce these challenges.

Heterogeneity In Pathway Definition

Pathway data integration and interpretation is challenging due to the diversity of pathway definitions. Since pathways are models created by human experts, the same pathways, as represented in different databases, may contain different proteins and reactions, and likely will have different names. For example, while Hedgehog signaling is a single pathway in KEGG, Signalink2.0 (Fazekas *et al.*, 2013) has divided it into Hedgehog-core and Hedgehog-nonCore pathways. These three pathways only partially overlap. Due to this heterogeneity, most integrated pathway databases store pathways from different sources as separate pathways. One consequence of this approach is redundancy of data that usually leads to long lists of pathways as annotation and enrichment analysis results. This makes interpretation of the results challenging. Word-clouds (Herwig *et al.*, 2016) and term enrichment analysis (Rahmati *et al.*, 2017) are two effective strategies that partially solve this problem; however, neither of them can fully resolve it.

PathCards (Belinky *et al.*, 2015) has tried to tackle redundancy and heterogeneity in pathways content and names by consolidating pathways of related processes in super-pathways (using genes). An “onion” model, introduced by Signalink2.0, defines core and non-core pathways, and provides one potential solution to this problem. PathCards also uses a modified version of this strategy to define super-pathways and sub-pathways in a multilayer system by scoring membership of each gene in each super-pathway based on the frequency of appearance of that gene in source pathways under that super-pathway. PathCards first clusters pathways by computing a pairwise Jaccard Similarity, and applying a two-tier clustering approach that combines hierarchical clustering and nearest neighbor joining. In order to name each super-pathway, they use name of the member of each cluster (super-pathway) that is most highly connected to other members of the cluster. Using this approach, they reduce the number of pathways from 3215 across 12 different sources to 1073 super-pathways in PathCards. The frequency-based score is next used to assign the strength of membership of each gene in a super-pathway, i.e., forming the “onion” model. However, the authors have highlighted that most super-pathways comprise pathways from two sources, with a maximum of five sources in each super-pathway, which is attributed to the inherent biases in content of single pathway databases (Belinky *et al.*, 2015).

Our analysis confirms that pairwise pathway overlap alone is not sufficient as a similarity measure to accurately consolidate pathways. Fig. 3 shows hierarchical clustering of 4976 core pathways integrated in PathDIP from twenty major pathway databases. Using the Jaccard Similarity of pathway pairs according to their protein overlap as a similarity measure of the processes that they describe, we investigated members of different clusters, as well as the relative positions of the same processes from different source databases, on the clustering tree. Interestingly, pathways from the same database are frequently clustered closer to each other than the same processes from different databases. Consistent with our earlier examples in this article, we focused on the Hedgehog pathway. After cutting the clustering tree at height 1.5 (maximum height of tree is 8.65) we found 1378 clusters out of which 7 contained at least one Hedgehog pathway (clusters number 9, 25, 75, 520, 1312, 1365, and 1366). In Fig. 3(B-D) we highlight clusters #9, #520, and #1366. While in cluster #1366 four Hedgehog pathways from four different sources are grouped together (Hedgehog Signaling from Signalink, SIGNOR, and NetPath, and “Signaling events mediated by Hedgehog family” from PID) (Fig. 3(B)), cluster #512 has only one member which is “Hedgehog signaling events mediated by Gli proteins” from PID (Fig. 3(C)), and cluster #1366 includes only one Hedgehog pathway from Reactome (“Hedgehog ligand biogenesis”), which is grouped with 31 other pathways, out of which only one pathway is not from Reactome. Non-canonical NFκB signaling, protein degradation/proteasome, regulation of apoptosis, and p53-related pathways form four groups of pathways in this cluster, all of which have Reactome as their source database (Fig. 3(D)). This divergence in clustering of similar processes from different databases further highlights the heterogeneity of the contents of pathway databases, and the necessity to develop effective pathway annotation, integration, and consolidation methods.

Another major challenge in pathway consolidation is the ambiguous terminology that pathway databases use. For example, “mRNA splicing” and “Spliceosome” have been used for the same process in Reactome and KEGG, respectively. Similarly, “Hedgehog Signaling” in Wikipathways is referred to as “Signaling events mediated by Hedgehog family” in PID. Defining a consensus controlled vocabulary, or pathway ontology can help address this problem.

Pathway Curation

Manual pathway mining

Primary pathway databases are created and fully depend on manual curation of papers by experts. Since the beginning of pathway databases in 1995, these databases have been enhanced in many respects, and proteome coverage has been increased by data integration. Currently, pathDIP (version 3) includes 4976 pathways and represents 212,155 pairs of literature curated protein-pathways associations among 12,742 unique human protein-coding genes. Although several computational techniques for *de novo*

Fig. 3 (A) Clustering of 4976 pathways from 20 pathway databases (obtained from PathDIP v.3) based on their gene content overlaps is not sufficient for consolidating pathways effectively. (Color coding shows Jaccard Similarity of gene content of pathways.) In order to illustrate the divergence in pathways that are grouped in close clusters, we cut the clustering tree at height 1.5 (max 8.65) and found 1378 clusters. At this cut-off level, cluster sizes are small enough to plot them. Surprisingly, cluster members are highly divergent, even though the cut-off distance is very small. Using Hedgehog pathway as an example, we found seven clusters had at least one hedgehog pathway (#9, 25, 75, 520, 1312, 1365, and 1366). In this example, we have located two of these furthest clusters and one cluster in the middle, i.e., (B) cluster #9, (C) cluster #520, and (D) cluster #1366.

pathway prediction (or protein-pathway association prediction) have been developed, curated pathways remain the main source of high quality pathway definitions (with documented provenance, accuracy, and details).

However, pathway curation is slow and prone to errors and inconsistencies due to the above-mentioned ambiguities in protein and pathway naming. Furthermore, depending on the purpose of a study, the focus of a database, and the expertise of individual curators, different information can be extracted from the same paper and organized into different ontologies. For example, Reactome (V60) includes two sets of pathways, “PKB mediated events”, and “AKT phosphorylates targets in the cytosol”. Both sets include pathways and reactions related to the AKT1 gene, but while the second set includes the correct gene name in the pathway title, the first set includes the old nomenclature of AKT1 (PKB). Not surprisingly, these two pathway sets were curated and reviewed by different curators, in 2006 and 2015, respectively. It is easy to imagine how challenging it can be to integrate pathways with such nomenclature variability, and how difficult it can be to identify overlapping reactions from the two sets of pathways if the main gene is named differently (for example, the reaction describing AKT phosphorylation of TSC is called “AKT phosphorylates TSC2, inhibiting it” in one set and “Phosphorylation of TSC2 by PKB” in the other set).

The level of confidence in the experimental methods that have been used in source papers is another issue that usually is not recorded by pathway curators. Hence, the reliability of different modules of a pathway that have been extracted from different papers, can be inconsistent. Moreover, manual curation is prone to human errors. Schnoes *et al.* have reported a high rate of molecular function mis-annotation in six superfamilies of enzymes in KEGG (average ranging from 22% to 63% for each of the six enzyme clusters) that they attribute to misinterpretation by human curators (Schnoes *et al.*, 2009). Over 80% of these errors were identified as over-annotation, i.e., specificity levels higher than what the source paper implied. Such errors easily propagate into pathway databases and influence the interpretation of experiments.

Automatic pathway mining

Over the last decade several automatic literature mining approaches and expert pathway search engines have been implemented to accelerate biomedical literature curation (including, but not limited to, pathways) (Luo *et al.*, 2014; Subramani *et al.*, 2015; Ravikumar *et al.*, 2014a,b). However, automatic pathway curation is a challenging task that has several steps, including concept detection, document classification, information extraction, and ontology construction (Ravikumar *et al.*, 2014a,b), each of which is a research field in computer science. We refer the reader to (Ravikumar *et al.*, 2014a,b; Huang and Lu, 2016) for a detailed discussion of challenges in biomedical and pathway text mining systems.

Pathway Context

Pathway consolidation and pathway enrichment analysis are strongly affected by the context in which processes and signaling in a given pathway are defined. For example, most genes are part of several pathways, and their activity and relationship with those pathways can vary across different conditions/contexts. Annotating pathways with context information is challenging as it requires details about which part of the pathway is invariant to existing conditions, and which part may be context-specific; it is especially difficult since, in most cases, such information is not available.

Due to the importance of context in using and understanding pathways, more recently-developed pathway databases and tools have included predicted context to their analysis (Moulos *et al.*, 2013; Pinto *et al.*, 2014; Kuperstein *et al.*, 2015). Furthermore, context-specific pathway databases such as NetPath (Kandasamy *et al.*, 2010), PID (Schaefer *et al.*, 2009), RB-pathways (Calzone *et al.*, 2008), and PharmGKB (Whirl-Carrillo *et al.*, 2012) have been developed, focusing on phenotype-specific pathways (e.g., cancer) or condition-specific pathways (e.g., effect of a drug on a signaling cascade). Similarly, general-domain pathway databases, including KEGG and Reactome, have developed pathway categories, for example drug pathways or disease-specific pathways.

Despite these recent efforts, recording context during manual curation and considering it in designing pathway ontologies has not been traditionally part of the pathway annotation and sharing process. Although the importance of context is becoming more evident, the type and level of detail that is included as context differ across databases. Therefore, depending on the workflow, specific databases or even the original papers may be the best and the most accurate source of information. To further aid in this effort, expert data mining systems have been developed (Kemper *et al.*, 2010; Miwa *et al.*, 2013). The common concept behind these systems is to provide search engines with which users can find literature evidence for a process, pathway, or a part of it. Through these efforts, existing primary and integrated (hybrid) databases may be further expanded to provide both broad coverage and an increased, more homogeneous, level of detail across proteins and pathways.

Summary and Concluding Remarks

Over the past two decades, pathway databases have expanded in numbers, coverage, and richness of annotation they provide. They are an integral part of most of bioinformatics workflows used to understand system-level effects, for example immune response to stress or therapy (Brodin *et al.*, 2013), using previous knowledge. They are an essential component of pathway-targeted cancer-drug therapy methods (reviewed in Yauch and Settleman (2012)); offer insight in HTP data analyses such as gene and protein expression, and genome assembly and annotation (Braun, 2014) through enrichment analysis; and help establish the relevance of genotypes and phenotypes (Carter *et al.*, 2013; Chang *et al.*, 2015). Currently, several hundred pathway databases are freely available, each of which groups and annotates genes and their relationships at different levels of detail and context.

Data sharing and access support also vary across databases, with many providing data in diverse file formats and offering different analysis techniques and algorithms (reviewed in García-Campos *et al.* (2015)). To improve the consistency and speed of curation, diverse software for editing and visualizing pathways and their analyses results have been produced. (Table 1) summarizes these specifications of major pathway databases.

Despite all these achievements, several challenges remain. Although each of these challenges has its specific steps to be resolved, one common cause behind most of them is the lack of standard protocols for paper curation, and the lack of a common pathway ontology. Defining standards for pathway extraction, annotation, organization, and sharing of biological data has successful examples. IMEx (International Molecular Exchange Consortium) for example, is an international effort to define standards for protein interaction data providers to share their curation efforts and decrease redundancy in protein interactions (Orchard *et al.*, 2012). Similarly, BioPAX is an international initiative to facilitate pathway data exchange among pathway data providers (Demir *et al.*, 2010). While BioPAX is implemented as an ontology for pathway data sharing, it only provides a framework in which different ontologies can be defined. For example, KEGG and Reactome have defined their ontologies differently, both of which are deliverable through BioPAX. However, the current version of BioPAX (v3) does not define a standard controlled language (ontology) for sharing pathways. Although efforts such as INOH (Yamamoto *et al.*, 2011) and the Bioportal Pathway Ontology (Petri *et al.*, 2014) are focused on defining ontologies for pathway data, no consensus ontology has been accepted. Defining such a structured vocabulary, along with standard protocols for pathway curation, and formats for storing and sharing data (such as BioPAX) can overcome most of the current major issues in curation, sharing, and integrating pathway data, and increase consistency across different databases. Such improvements would also facilitate development of more efficient automatic pathway curation systems.

Despite their incompleteness and heterogeneity, pathway databases are crucial resources in current systems and molecular biology. While there are certain steps that need to be taken to improve quality of pathway data and their consistency, data mining, data annotation and integration, and *de novo* pathway prediction techniques are among the most promising directions for further improvement of pathway databases. They will improve the coverage, consistency, and depth of pathway data, enabling diverse bioinformatics workflows, and aiding systematic and comprehensive exploration of signaling processes in diverse biomedical contexts.

Biographical Sketch

Sara Rahmati is a PhD candidate in Medical Biophysics, University of Toronto, Canada. She is interested in developing algorithms to extract and analyze information from high-throughput biological data and sizable cellular networks. Her PhD focus is on mining different types of biological data and integrating them through statistical, machine learning, and big data visualization techniques. She applies these techniques to predict functions and context of activity of protein interactions and cellular pathways. She is also experienced in developing computational methods in predictive structural biology and working with open-source protein docking software. Sara finished her Master's degree in the School of Computing, Queen's University, Canada and her Bachelor of Science in Computer Engineering, Isfahan University of Technology, Iran.

Chiara Pastrello is a research associate at University Health Network, Toronto. She is interested in cancer genetics and epigenetics, that she formalized in her medical genetics residency – focusing on the prediction of pathogenicity of unclassified variants in mismatch repair genes. She is further interested in cancer systems biology, specializing in network analysis, and the curation of expression data for multiple databases maintained at Prof. Jurisica lab. Her current research interests include the study of microRNAs in cancer signaling to distant metastasis, as well as the application of network analyses to study molecules and pathways playing a central role in cancer.

Andrea E.M. Rossos is a third-year undergraduate student in a Bachelor of Science program in Honors Biology at McMaster University, Canada. She was a Princess Margaret Summer Student who has worked in the Jurisica Lab for summer 2016 and summer 2017 as a recipient of the Ian Lawson Van Toch Internship Award in Cancer Informatics. Andrea has been involved with data curation and development for projects such as mirDIP (microRNA Data Integration Portal), CDIP (Cancer Data Integration Portal) and ADIP (Arthritis Data Integration Portal). Andrea has also been involved with projects looking at the properties and diversity of biomolecule (miRNA, protein, etc.) databases. Andrea's current research interests are the prognostic and diagnostic roles of microRNAs and other biomolecules in cancer and disease.

I. Jurisica is Tier I Canada Research Chair in Integrative Cancer Informatics, Senior Scientist at Princess Margaret Cancer Centre, Professor at University of Toronto and Visiting Scientist at IBM CAS. He is also an Adjunct Professor at the School of Computing, Pathology and Molecular Medicine at Queen's University, Computer Science at York University, affiliate scientist at the Institute of Neuroimmunology, Slovak Academy of Sciences, and an Honorary Professor at Shanghai Jiao Tong University. Since 2015, he has also served as Chief Scientist at the Creative Destruction Lab, Rotman School of Management. He has published extensively on data mining, visualization and cancer informatics, including multiple papers in *Science*, *Nature*, *Nature Medicine*, *Nature Methods*, *J Clinical Oncology*, and has over 11,167 citations over the last 5 years. He has been included in Thomson Reuters 2016, 2015 & 2014 list of Highly Cited researchers, and The World's Most Influential Scientific Minds: 2015 & 2014 Reports.

Visualization of Biological Pathways

Giuseppe Agapito, University "Magna Graecia" of Catanzaro, Catanzaro, Italy

Introduction

This article deals with theories and algorithms for drawing and displaying networks, with particular emphasis on biological Pathways. Drawings are an attractive and effective way of conveying information. Networks drawing includes all aspects of visualizing structural relations between objects, not easily highlighting using other ways of representation. But, how to determine which automatic network generation produces a good or wrong visualization of the information? The best drawing for networks may not exist. Human perception of the same drawing changes from individual to individual and different application domains require different kinds of drawing. Thus, it is needed to define some constraints to take into account, in order to produce good results.

Biological Pathways Representations

Networks in general, as well as biological pathways, can be represented using a mathematical formalism called *Graph*. Graphs are abstract objects, with the ability to describe relations between objects. Formally, a graph G consists of a finite set of vertices (*objects*) and a finite set of edges (*relations*). The vertices of a graph are sometimes called nodes or dot; edges are sometimes called links, lines, arcs or connections. The set of vertices of G is denoted by $V(G)$ and the set of edges is denoted by $E(G)$. In a short form a graph can be write as: $G=(V, E)$. An graphical example of graph is depicted in Fig. 1.

The number of vertices of a graph G is its *order*, written as $|G|$; instead, its number of edges is denoted by $|G|$. A graph of order 0 or 1 is called trivial. A vertex v and an edge e are incident if $v \in e$; thus e is an edge of v . Two vertices are with an edge and are called *endvertices* or *ends*, and the edge is known as ends join. An edge (v, w) is usually represented as vw or (uv) . Two vertices x and y of G are adjacent, or neighbours, if (x, y) is an edge of G . Two edges $e \neq f$ are adjacent if they have an end in common. A Graph G is complete if and only if, all its vertices are pairwise adjacent. The *degree (or valency)* $dG(v)=d(v)$ of a vertex v is the number $|E(v)|$ of edges at v ; this is equal to the number of neighbours of v . A vertex of degree 0 is isolated. A *path* is a non-empty graph $P=(V, E)$ of the form $V=\{x_0, x_1, \dots, x_k\}$, $E=\{x_0x_1, x_1x_2, \dots, x_{k-1}x_k\}$, where the x_i are all distinct. The vertices x_0 and x_k are linked by P and are called its ends; the vertices $x_1, \dots, x_{k-1}$ are the inner vertices of P . The number of edges of a path is its *length*.

If every edge has none direction (joins an unordered pair of vertices) the graph is called *undirected*, this means that, it is possible walk through the edge in both direction; the edge (x, y) is the same of (y, x) . Otherwise, if the edge has a direction associated the

Fig. 1 Graph example.

Fig. 2 Directed acyclic graph.

graph is called *directed graph* or *digraph*. Directed graphs are employed to model *signal transduction pathways* and *gene regulation networks*. Furthermore, if the digraph does not contain cycles is called **Directed Acyclic Graph (DAG)**. An example of DAG is shown in Fig. 2.

A cycle is an edge that joins a vertex to itself i.e. an edge (x, γ) with $x=\gamma$. Sometimes, it is needed to draw graphs where it is possible to have both edges with or without orientation. A graph extension able to represent and to manage correctly the two different types of edges is called **Mixed Graph**. A mixed graph G consists of three finite sets: the set of vertices $V(G)$, the set of undirected edges $E(G)$ and the set of directed edges $\vec{E}(G)$, and in short the graph can be written by means of the following triple: $G = (V, E, \vec{E})$. An example of mixed graph is shown in Fig. 3.

Cell signaling pathways are commonly represented using mixed graphs (Ma'ayan, 2009) in which some edges represent activation or inhibition relations, whereas other types of edges represent physical protein-protein interactions without a clear-cut directionality such as binding to anchors and scaffolds (Ma'ayan et al., 2005). The kinetics of a biochemical reaction is the rate that measures the effects of varying the conditions of the reactions under investigation. Kinetics of biochemical reactions can be represented through **Weighted Graph** (Bhalla and Iyengar, 1999). Thus, information may be attached to the nodes or arcs of a graph or both, where: the nodes are called labeled, and the arcs are called weighted. An example of a weighted graph is depicted in Fig. 4.

A weighted graph is, therefore, a particular type of labeled graph in which each edge is given a numerical weight (usually not negative). For example, in cell signaling: graphs can represent other properties of edges such as interaction weights by means of labels (Ma'ayan, 2009). When a graph contains only binary relations between the vertices, the graph is called: *Ordinary Graph* or *Simple Graph*, otherwise we have a *Hypergraph*. In Fig. 5 is shown an example of hyper graph.

Fig. 3 Mixed graph.

Fig. 4 Weighted Graph.

Fig. 5 Hyper graph.

Fig. 6 Multi graph.

Hypergraphs offer a formalism that helps to overcome such conceptual limitations. As the name indicates, hypergraphs generalize graphs by allowing edges to connect more than two nodes, which may facilitate a more precise representation of biological knowledge (Klamt *et al.*, 2009). For example, in biology, the nodes typically describe proteins, metabolites, genes, or other biological entities, whereas the edges represent functional relationships or interactions between the nodes such as “binds to”, “catalyzes”, or “is converted to”. Many biological processes, however, are characterized by more than two participating partners and are thus not bilateral. A metabolic reaction such as $X + Y \rightarrow Z + T$ (involving four species), or a complex protein consisting of more than two proteins, are typical examples. As mentioned above, between a pair of nodes can exist more than one interaction (edge) with a different function and meaning. In this case, a pair of nodes are related in several different ways, from *multiple* or *parallel edges*, and in order to correctly represent this occurrence it is needed to use the *Multigraph* formalism.

A possible representation of the multi graph is depicted in Fig. 6.

Unlike a simple graph, a multigraph gives the formalism necessary to overcome the issues related to the management and representation of multiple edges connecting a pair of vertices. The close interplay between the p53/MDM2 pathways (Larsson and Girnita, 2005) is an interesting example where multigraph can help to describe and represent the interaction correctly among the nodes of the graph, with the advantage to simplify the phenomena to convey. Furthermore, if all multiple edges have a direction, the graph is called *Quiver* or *Multidigraph*. From the description above of the different types of existing graphs and their properties, it is possible to say that: graphs represent a very powerful tool to use in order to simplify the representation and the analysis of biological networks.

Paradigms for Graph Drawing

Depending on the context, the essential features of a graph should be drawn in different ways. Nodes may be drawn as dots, circles, boxes, or represented implicitly by their name labels. Edges may be drawn as straight lines, dotted lines, or bends. The information corresponding to the nodes and edges can be visualized using text labels at various positions in or next to a graph object, different colors, or other visual elements such as the thickness of lines, the size of boxes, etc. Moreover, a graph may be drawn in the 2D plane or three dimensions 3D. Once decided upon the representation, the question of how to convey the nodes and edges of a graph must be faced. A drawing, is a mapping of nodes and edges. But what distinguishes a good representation from a bad one? For example, drawing a *Entity Relation Diagram* with an algorithm designed to draw *Protein Protein Interaction Networks* will most likely produce a highly unsatisfactory picture. That is because an algorithm thought to draw a graph related to the protein-protein interactions network also uses some general knowledge on protein interactions. Also, for example, users would be highly confused if entities or relations were drawn in locations that highlight network topology features as hub or cliques, instead of locations that highlight in a remarkable way the connections among tables into the database. On the other hand, biologists would expect that the drawing reflects the results of the interaction; in order that, proteins involved in the same process are drawn next to each other for example. So for every particular graph drawing problem, we need especially customized algorithms which look beyond the structural properties of the given graphs and also use additional knowledge about the semantics behind the graph structure. This seems to imply the need to have a high number of different graph drawing algorithms. Fortunately, this is not true. There are a few general concepts and techniques which are powerful enough to cover a broad range of graph drawing applications. Thus, it is needed to specify some concepts able to describe the requirements of a nice drawing. First of all, it is necessary to define a drawing convention. Drawing convention defines the basic rules that the drawing must satisfy in order to be *admissible*. For example, in drawing biological pathway networks for a software application, it is possible to adopt the conventions where proteins are represented as a circle, whereas biochemical reactions are represented as a triangle, etc. Furthermore, there is the need to introduce a different type of edges able to describe every interaction among the different element that composes the pathway. From these examples, it is possible to note that the drawing conventions of a real-life application are very complex and involve the analysis of many details to take into account.

A short list of the most used drawing convention is the following.

- *polyline drawing*: each edge is drawn as polygonal chain (see Fig. 7);
- *straight line drawing*: each line is drawn as a straight line (see Fig. 8);
- *orthogonal drawing*: each edge is drawn as polygonal chain of alternating vertical and horizontal line (see Fig. 9);
- *planar drawing*: drawing without crossing edges (see Fig. 10).

Fig. 7 Polyline drawing.

Fig. 8 Straight line drawing.

Fig. 9 Orthogonal drawing.

Fig. 10 Planar drawing.

The second criteria to take into account is to specify some properties of the drawing that would be applied as much as possible to improve readability. Finding a good arrangement is thus reduced to optimizing one or a few criteria. In algorithms where the primary goal is to produce layouts for human these criteria are called aesthetics criteria for a readable drawing; instead, technical criteria are on technological constraints such as: avoid crossing edge in drawing schema of electrical circuits. A short list of the most used aesthetics criteria for their practical importance is: *Crossing edge minimization*. Minimization of the total number of overlapping edges. If too many edges cross each other, the human eye cannot easily find out which nodes are connected by an edge. If a graph may be drawn without edge crossings (such graphs are called planar), this is very often preferable to a drawing with edge crossings. *Bend minimization*. Minimization of the total number of bends along the edges. This is an important aesthetics criterion for orthogonal layouts because the human eye can much more easily follow an edge with none or only a few bends than an edge wildly zig-zagging through the picture. *Maximum bends minimization*. Minimization of a maximum number of bends on edge. *Uniform bends minimization*. Minimization of the variance of the number of bends on edge. *Area minimization*. Minimization of the total area required for the draw. The ability to construct area efficient drawings is essential in practical visualization applications,

where saving space is a fundamental property. Moreover, a draw looks much better if the nodes and edges fill the space with homogenous density. *Symmetries*. If a graph contains symmetrical information, then it is important to reflect this symmetry in its arrangement. Symmetries can be further formalized introducing a mathematical model of symmetries in graph and drawing, but unfortunately, displaying symmetries is not an easy task. *Clustering*. When drawing huge networks such as biological or social networks gathering together similar nodes, can help to create a filter or reveal some of the graph's structure, and at the same time may increase the graph readability. *Total edge length minimization*. Minimization of the sum of the lengths of the edges. This criterion is meaningful if and only if the drawing strategy adopted prevent from being arbitrarily scaled down. *Maximum edge length minimization*. Minimization of the maximum length of an edge. This criterion is meaningful if and only if the drawing strategy adopted prevent from being arbitrarily scaled down. *Uniform edge length minimization*. Minimization of the variance of the lengths of the edges. *Angular resolution maximization*. Maximization of the smallest angle between two edges incident on the same vertex. This constraint is very significant in straight line drawing. The third criteria of a graph drawing algorithm is related to the computational efficiency. This is a crucial aspect of graphs drawing algorithms, that can ensure good performance (real time response), even for large graphs. This feature becomes a critical issue when graph analysis is in progress and users can navigate without delay the graph, as well as to guarantee real-time response. The aesthetics criteria are computationally hard, and on the other hand are in contrast with the other criteria, and it is very complicated to deal with all them at the same time. The reason for which there is the need to define approximation strategies and heuristics to get a compromise among the three criteria described before, in order to produce readable graphs.

Layout Algorithms

The purpose of data presentation is to reveal information buried in a set of data either to the exploration or just in its communication. A display is said to be effective if it conveys the real information in an easily comprehensible, yet precise, way. Graphs are used as abstractions in numerous fields of application. Consequently, the same structure can mean quite different things depending on the context. To effectively visualize a graph, the specific type of information it represents must govern the graphical design. The reason for which, graphs represent an important way to convey any information about connections, like computers, social, chemical or biological networks, which can be modeled as objects and relationship between these objects. These relationships are critical because they allow studying the problem in a graphic way, highlighting some characteristics not easily remarkable in other ways.

Visualization is an important way to analyze graphs. To provide visualization tools able to deal with networks their core has to comprises a layout algorithm, i.e. an algorithm able to decide how to present each object of the graph to the user. For this purpose, some layout algorithms were developed, in order to satisfy the drawing convention, some aesthetic criteria (the most useful related with the data to draw), in order to guarantee an excellent computational efficiency.

A concise description of the most known layout algorithms and their features (not go too far into the technical details) is presented below:

- **Random Layout Algorithm:** is very simple, because it arranges the graph nodes and edges in a random way on the screen. The advantage of this algorithm is its simplicity for both implementation and use, but on the other hand, it presents some disadvantages as a high number of cross-edges, a not optimum use of available space with large dimension graphs. Furthermore, the random layout is used to idealize architectures for dynamical models of genetic networks S.A. and [Kauffman \(1969\)](#).
- **Circular Layout Algorithm:** how the name suggests, the algorithm places the graph nodes in succession, one after the other follow in a circular arrangement. Thus, all nodes are at the same distance from the center of the screen, attempting to minimize overlapping vertices and cross edges (also known as overlapping edges). Although this algorithm can appear common, it is widely used to visualize complexes and pathways ([Tsay and Wu BL, 2009](#)).
- **Hierarchical Layout Algorithm (HLA):** has been developed by Sugiyama ([Sugiyama et al., 1981](#)) to reduce the number of cross edge, by arranging the graph nodes in different hierarchical groups. The HLA is scalable, efficient, and yield pleasant layouts for sparse graphs, even if the number of nodes is huge. A drawback of HLA is related to the computational efforts to minimize the production of overlapping edges. These kinds of problems belong to the class of NP-complete problems, that prevents the use of HLA for large graphs (with about a thousand of nodes and edges respectively). In addition, the hierarchical layout is used to dynamically visualize the complex data related to pathways ([Becker and Rojas, 2001](#)).
- **Fruchterman&Reingold and Eades&Peter Algorithms.** Fruchterman&Reingold algorithm ([Fruchterman and Reingold, 1991](#)) and Eades&Peter algorithm ([Eades, 1984](#)), also known as Spring Embedded Algorithm, belong to the class of Force-Directed Algorithms (FDA). FDA re-represent each node as an electrically charged item and each edge as a spring connecting two nodes. Thus, nodes with the same charge repel each other, while opposite nodes attracting each other, with an attraction/repulsing force due to the springs. These algorithms iteratively compute a distribution for each node determinate by the forces until the equilibrium is obtained. The computational time required to get the convergence to equilibrium grows rapidly with the size of the graph (that is, the number of nodes and edges) and the layout process becomes time-consuming for large graphs. The force-directed layout is commonly included in the majority of visualizations tools of biological networks ([Kojima et al., 2007](#)).
- **Kamada-Kawai Algorithm.** The algorithm developed by T. Kamada and S. Kawai is derived from the concept of theoretic distance between the nodes ([Kamada and Kawai, 1989](#)), i.e. the length of the shortest path among nodes. In this algorithm, the

forces among the nodes can be computed on their graph theoretic distances, determined by the lengths of shortest paths between each couple of nodes. The forces in the Kamada-Kawai algorithm, are represented as spring which force is directly proportional to the graph-theoretic distances. The Kamada-Kawai algorithm is more complex to encode on Fruchterman&Reingold or Eades&Peter algorithms but on the other hand provides excellent results.

- **Tree Layout Algorithm:** disposes graph as a tree without cycles, through a hierarchical organization of the nodes, producing clear and easy to understand visualization. The main advantage of the Tree Layout algorithm is its low complexity (generally, it presents linear performance in the number of nodes both for binary and *n*-ary trees) how explained in [Reingold and Tilford \(1981\)](#), making it efficient and scalable, even with large graphs. On the other hand, Tree Layout algorithm presents problems arranging a huge number of nodes in limited areas as the monitor. Finally, the Tree Layout algorithm provides a natural way to visualize the global structure of a complex pathways ([Tsay and Wu BL, 2009](#)).
- **Simulated Annealing Algorithm.** The name and inspiration come from the annealing in metallurgy, a technique involving heating and controlled cooling of material to increase the size of its crystals and reduce their defects. In fact, the structural properties of a solid depend on the rate of cooling (big crystals are obtained if the rate of cooling is slowly enough). The Simulated Annealing (SA) algorithm represents the space of the visualization problem as a set of states each one with associated energy, and it tries to find the state with minimum energy (i.e. below a threshold) that represents a potential solution. In particular, the SA may be applied to optimize different objective functions, for instance, a common goal could be minimizing the number of overlapping edges. Other works ([Zhang et al., 2010](#)) use SA to highlight the biological modules of the protein interaction networks by maximizing some quantitative measures such the modularity density, that is a measure for describing the modular organization of a network. The simulated annealing (SA) algorithm includes the following main steps:
 1. Random selection of a starting point among all possible solutions, although more sophisticated techniques can be used.
 2. Next solution selection and assessment, SA iteratively selects a point nearby of the current solution and determines whether the new point is better or worse than the current point. If the new point is better than the current one it becomes the next point otherwise, if the new point is worse than the current one, the algorithm can still choose the next point to explore, escaping from the local minimum (or maximum). This evaluation is done by an opportune assessment function.
 3. Stop criterion determines the end of the algorithm. The principal stop criteria are: the absence of changing of the value of the objective function, the average change in the value of the objective function is down respect to a defined threshold, or the number of iterations overcome the maximum number of iterations.

Simulated annealing has been successfully applied to the layout of general undirected graphs. The main drawback of SA algorithm is that the search space grows with the number of the nodes, becoming time-consuming with large graphs.

- **Cluster Layout Algorithm.** The Cluster Layout algorithm decrease the number of visible elements, reducing the visual complexity of the graph. Reducing the number of visible nodes and edges allow to improve the readability increasing in the same time the performance of layout and rendering ([Clemencon et al., 2011](#)). To get good results, clustering requires the definition of an appropriate metric that able to evaluate the similarity between nodes (or the distance). The metric can be *content-based* if it uses information associated with the content of the node, or *structured-based*, if it uses information on the structure of the graph. It is worthing to note that the Cluster Layout algorithm can be used to develop efficient functions such as filtering and search.
- **3D Layout Algorithm.** It is a popular technique to display graphs in 3D instead of 2D ([Ware et al., 1997](#)). The third dimension adds more available space, making easier the visualizzation and the navigation of large networks as well as biological pathways. As a consequence, 3D Layout algorithms have to enclose new features not present in 2D Layout algorithms, such as *transparency*, *depth*, *perspective*, navigation and so on. Furthermore, 3D Layout algorithms must allow to the users to interactively navigate the graph, modifying in real time the graph view based on the moving around the nodes. This improve the user navigation experience but in the same time, it adds further difficulty in handling the graph perspective.
- **Grid Layout Algorithm.** Grid Layout algorithm disposes the graph nodes on a 2-dimensional squared grid. Into the grid, the nodes are modeled as particles interacting together. Grid Layout algorithm model the graph as a system of interacting particles on a grid. The particles (nodes) interact according to a cost function which is designed based on the topological structure of the network. In such a system, closely related nodes attract each other, and remotely related nodes repulse each other. In [Li and Kurata \(2005\)](#), a Grid Layout algorithm to draw complex biochemical networks is proposed, helping researchers to gain insight into the complex network data.

Introduction

The notable improvements of bio-nano-technologies have allowed the fast production at affordable costs of increasing amounts of reliable data of different types. They comprise mainly biomolecular data which describe the observed biological processes, either physiological or pathological, from different perspectives; thus, considering them comprehensively can allow highlighting new insights on complex patho-physiological phenomena.

On the other hand, the development of information and communication technologies (ICT), as well as of data mining and machine learning techniques, makes easier processing the many generated data to automatically annotate them, and create repositories where to store them and make them publically accessible. In particular, the progress of sequencing techniques and the development of new technologies for automatic high-throughput analysis and annotation are producing a huge number of biomolecular data and knowledge.

Such multiplicity of very valuable data and information is sparsely stored in many heterogeneous and distributed databases that continuously increase in number, size and coverage (Galperin *et al.*, 2017). This creates a pressing need for integrative structures that are able to simplify the accessibility to the data and to decrease – if not to remove – both the variety of semantic representations of the data, and the data redundancy, which is unfortunately often present both in a single and among different biomedical-molecular databases (Louie *et al.*, 2007; Goble and Stevens, 2008). Integration of heterogeneous data is a challenging task, particularly in biology where the amount of data sources and data types increase rapidly, which involves issues such as data integrity, consistency, redundancy, connectivity, expressiveness and updatability. Integrative bioinformatics addresses these aspects by providing approaches and methods for the unified access to life science data, supporting searching and analysis of these data for the extraction of new knowledge from all the available data (Chen and Hofestädt, 2014).

After this introduction, this article first describes and discusses the main data integration approaches that have been proposed and used in bioinformatics. Then, it focuses on more advanced approaches for data integration, i.e., ontology-based, statistical and network-based, which allow for a semantic and biologically-driven integration of the data considered in bioinformatics and computational biology.

Data Integration Approaches

Many diverse approaches and implementations have been suggested to integrate distributed heterogeneous data, with notable applications in bioinformatics; they comprise *information linkage* (e.g., SRS (Etzold *et al.*, 1996), NCBI Entrez (Tatusova *et al.*, 1999)), *federated databases* (e.g., BioKleisli (Davidson *et al.*, 1997), BioMart (Smedley *et al.*, 2009)), *multi-databases* (e.g., TAMBIS (Stevens *et al.*, 2000)), *mediator-based solutions* (e.g., BioDataServer (Freier *et al.*, 2002)), Biomediator (Donelson *et al.*, 2004)) and *data warehousing* (e.g., EnsMart (Kasprzyk *et al.*, 2004), BioWarehouse (Lee *et al.*, 2006), Biozon (Birkland and Yona, 2006), GenoQuery (Lemoine *et al.*, 2008)). Despite many efforts have been performed, the problems regarding the creation, maintenance and updating of a public large and high-quality integration of originally distributed experimental and / or annotation data, which can aid discovering new biomedical knowledge via the reliable identification of missing annotations, keep being not fully solved yet.

Information Linkage

The *information linkage* approach for data integration aims to link together different information usually located in diverse resources without actually integrate them in a single place, but storing in a single place the references (i.e., links) to them in the location where they originally are; in this way, by following the integrated links it is possible to access the distributed data. It is one of the initial approaches used to integrate bioinformatics data. Its advantages are that it is quick to set up, easy to understand, and achieves a basic level of integration with minimal effort; conversely, its main disadvantages are that it does not include a cleaning and normalization of the data, does not have a way to directly integrate data from relational databases, and makes difficult to browse and mine the integrated data.

In the bioinformatics domain, some notable examples of implemented systems using this approach are the *Sequence Retrieval System* (SRS) and the *Entrez* system, both developed at the end of the last century.

SRS (Etzold *et al.*, 1996) is an information indexing and retrieval system that operates on databanks in a flat file or text format, such as some of those at the European Molecular Biology Laboratory (EMBL), supporting their data structure by providing special indices for implementing lists of sub-entities or hierarchically structured data fields. It provides a homogeneous interface to the entire flat file data within several biological databanks, retaining their original format; such interface enables users to access and query the contents of the databanks registered in the system, in order to navigate among them. Many elements are combined into the SRS system in order to

extend the power of normal retrieval systems, and to compete with the power of real databases, e.g., using a relational system, without compromising the rapidity. These components include languages for databank and syntax definition, a programmable parser, an indexing system, support for subentries, a system for taking advantage of links among databanks, and a query language.

The *Entrez* system (Tatusova *et al.*, 1999) was developed and implemented at the US governmental National Center for Biotechnology Information (NCBI) to manage large amounts of genome sequence data, and make them publicly available through the Web for data explorations beyond the flat file views that were traditional in those times. A highly enhanced and extended version of the *Entrez* system is still at present in use there. It is one of the most widely used interfaces to retrieve information from biological databases through simple text-based searches, linking and providing public access to the multiple and ample databases of biomolecular sequences, data and knowledge currently managed by the NCBI (Gibney and Baxevis, 2011). *Entrez* takes advantage of pre-existing logical relationships (expressed through Web-based links) between the individual entries in many public databases, which make sources interconnected so that any entry returned from one of the integrated sources also have related links to the other sources. These natural connections, mainly of biological nature, provide the ground for the method implemented in *Entrez*, through which all the information regarding a biological entity can be found avoiding sequential visits and queries to multiple distinct databases.

Federated Databases

The *federated database* approach is based on a meta-database management system (DBMS) able to map, transparently to the user, multiple independent databases into a single federated database. The individual databases composing the federation are interconnected by means of a computer network, and can be geographically distributed. In this approach each component database stays autonomous; thus, a federated database system is an alternative to merging the many single different databases composing the federation, which usually is an overwhelming job.

A federated, or virtual, database is hence the composition of all the component databases in the federated system; no integration of the data in the different constituent databases actually results from the data federation. Conversely, thanks to suitable data abstractions, a federated database system provides a homogeneous user interface that enables users to retrieve data from the multiple federated databases with a single query, despite the federated databases can be heterogeneous. To transparently support such functionality, a federated database system must be able to automatically subdivide a single user's query in sub-queries according to where the data addressed by the user's query are stored, submit each sub-query to the related relevant database of the federation, retrieve the answers of the individual databases, and compose them to provide an adequate result set answering the global user's query. Furthermore, since the federated databases can use different DBMS and query languages, the meta-DBMS must be able to apply wrappers to the sub-queries in order to translate each of them to the required and potentially different query languages.

Some notable examples of systems implemented with this approach in the bioinformatics domain are *BioKleisli* and *BioMart*.

BioKleisli (Davidson *et al.*, 1997) allows accessing various data sources important for the Human Genome Project (HGP) through the use of a framework that provides read access to multiple data sources containing biomedical complex structured data. Such framework includes three primary components: i) a powerful language to query and transform complex structured data, ii) an extensible architecture to implement the query primitives, and iii) optimization techniques that extend several known techniques to such more complex data types. The main limitation of *BioKleisli* is the lack of a global schema of the data in all the federated databases; thus, to express a query the user has to have a perfect knowledge of the data schema and structure of the federated sources integrated.

BioMart (Smedley *et al.*, 2009; Kasprzyk, 2011) is an open source data federation system originated at the European Bioinformatics Institute (EBI); it enables scientists to perform advanced integrated querying of biological data sources through a single Web interface regardless their physical location. Furthermore, *BioMart*'s capabilities are broadened through the integration with a set of widely used software packages, including DAS (Dowell *et al.*, 2001), Galaxy (Goecks *et al.*, 2010), Taverna (Hull *et al.*, 2006), BioConductor (Gentleman *et al.*, 2004), and Cytoscape (Shannon *et al.*, 2003). This makes possible using *BioMart* to address classical biological use cases, such as selection of single nucleotide polymorphism (SNP) for candidate gene screening, or annotation of microarray gene expression results. Being an easy to use, generic and scalable system it has been incorporated in well-known large data resources, such as Ensembl (Aken *et al.*, 2017), UniProt (The UniProt Consortium, 2017), COSMIC (Forbes *et al.*, 2017), and Reactome (Fabregat *et al.*, 2016).

Multi-Databases

A *multi-database* system is an integrated data system composed of a collection of autonomous database systems, typically heterogeneous, which contains a global descriptor for all the data in the component databases. It provides an integrated view through which the user can demand data management services on all the data in the integrated databases. Such integration requires the system to provide a mechanism for describing heterogeneous component databases, and to maintain an integrated description of all of them such that a user can view the multi-database as a single database.

The advantages of this approach, as well as of the federated database one, are that it is quick to be configured, its architecture is easy to understand (no knowledge of the domain is necessary), it achieves a basic level of integration with minimal effort, and it can wrap and plug in new data sources as they become available. On the other hand, it shows also several difficulties. In fact, it imposes constraints on original data sources, e.g., requiring that naming conventions across the integrated systems must be adhered to avoid inaccuracies in query results; it prevents performing query optimization across the multiple systems; if a source

system fails, the entire integrated application may fail; it is not readily suitable for data mining, or generic visualization tools; it relies on middleware technology, which often has performance (and reliability) problems.

One of the most renowned examples of multi-database systems in bioinformatics is *TAMBIS* (*Transparent Access to Multiple Bioinformatics Information Sources*) (Stevens *et al.*, 2000). Based on a knowledge model of the concepts and their relationships in molecular biology and bioinformatics, it allows biologists to ask rich and complex questions over a range of multiple bioinformatics information resources, such as databases and analysis tools, with a single interactive user interface. The used model of knowledge consists of a simple notion of the “things” that exist in bioinformatics and molecular biology, and how they are related to each other; this allows a biologist to browse it in order to see what can be expressed about “things” or concepts in molecular biology, and to join concepts together by their relationships so as to build new concepts.

Mediator-Based Solutions

The *mediator-based* approach defines a data integration architecture with two main components: wrappers and mediators (Fig. 1). The former ones are devoted to export information about data schemas, data and query processing capabilities of the data sources; the latter ones have the role of coordinating wrappers, by offering a unified view of all available data stored in a global schema, decomposing queries into smaller sub-queries executable by the wrappers, and lastly collecting the partial results and computing the final answer.

A mediator among the different data sources to be integrated is usually defined as the schema of a virtual database where the data sources are integrated; the mapping between each data source and the mediator (i.e., the global schema) must be defined. This involves several aspects to be addressed, including how to model the global schema, the sources, and the mappings between the two, and then how to verify the quality of the modeling process; how to construct the global schema, perform automatic wrapping of the sources (also considering existing limitations in the mechanisms to access the sources), and discover mappings between sources and global schema; how to process updates of the global schema and/or the sources; and how to answer queries expressed on the global schema and optimize query answering.

In the *mediator-based* approach, data extraction, cleaning, and reconciliation is at query run time, when a query expressed on the global schema must be automatically reformulated as a set of queries over the sources; the computed sub-queries are sent to the sources, and results are collected and assembled into the final answer. Such process must guarantee completeness of obtained answers, and efficiency in accessing the sources and computing the answers, which greatly depends on the adopted modeling of the data integration system; particularly, specification of the mapping between a source and the global schema can be source-centric, named *local-as-view* (LAV), when the sources are defined in terms of the global schema, or global-schema-centric, named *global-as-view* (GAV), when the global schema is defined in terms of the sources.

In the LAV method, the mapping gives a uniform query interface over the mediated global schema, directly supporting the query-answering by transforming a query over the global schema into specialized queries on the original data sources, which are modeled as views over the (nonexistent) mediated data schema. The burden of how to retrieve data from the sources is left to the query processor, but the benefit is that new sources can be added with much less effort than in a GAV system. Thus, the LAV method should be preferred when the mediated schema is more likely to change.

Conversely, in the GAV method the global schema is modeled as a set of views over the data sources where each element of the global schema is associated with a query over the sources; this simplifies answering queries over the mediated schema, leaving the complexity on implementing the mediator part regarding the retrieval of the data from the integrated sources. On the other hand, when a new source is integrated and/or an existing source changes its schema, the views for the mediated schema must be rewritten; thus, GAV is preferable when the sources unlikely change.

Fig. 1 Mediator-based data integration.

BioDataServer (Freier *et al.*, 2002) is an application example of the *mediator-based* approach in the bioinformatics domain; it proposes a data integration architecture implemented as a client-server system, which maps the user queries to the diverse and often limited query capabilities of the individual data sources. Given the very different query facilities, a common mechanism to process queries on the comprehensive database system is required; thus, the remote database access and integration process is reduced to a common set of simple operations that are executable by every wrapper.

Biomediator (Donelson *et al.*, 2004) is a similar system that performs data integration over multiple structured and semi-structured biological data sources. It uses a modular design and includes multiple components; one of them, the source knowledge base (SKB), contains i) all entities, attributes, and relationships in the mediated schema, ii) the catalog of all integrated data sources and the mediated schema elements mapping them, and iii) the mapping rules for bidirectional semantic translation of queries and source data flows. Notably, to describe the set of all integrated biological data and their interconnections the system uses an annotated mediated schema, and each user can define a completely customized mediated schema to specify his/her view of the set and express queries against it.

Data Warehousing

A usual approach in bioinformatics data integration is *data warehousing*, which consists of a priori integration and reconciliation of data extracted from multiple sources (Fig. 2). Typically, its construction is based on the extraction, transformation and load (ETL) process. During ETL, the initially dispersed data are first extracted from each of their original distinct source systems and temporarily stored in a staging database; then, they are transformed in order to both clean them (by detecting incomplete, incorrect, inaccurate, or irrelevant parts and correcting, replacing, or deleting them), and homogenize them for their integration. Finally, the cleaned and homogenized data are integrated in a data warehouse database, where they are arranged into hierarchical groups (called dimensions), facts, and aggregated facts, with a combination of facts and dimensions which is usually done according to a star data schema. To help users retrieving data from a usually complex data warehouse, on top of it data marts are typically created; they define subsets of the data in a comprehensive warehouse that regard specific topics or users.

Differently from other data integration approaches, in data warehousing the integration occurs at the lowest level, avoiding the need for the combination of queries and query results. All syntactic and semantic cleaning and harmonization of the data is performed a priori, during the data staging, allowing optimization of queries across data originally from multiple systems and faster query answering, independently on the original data sources, which remain untouched, and on their functioning; this is not possible in the other data integration approaches described. Furthermore, the data in a warehouse are readily suitable for data mining operations and generic visualization tools.

Besides these main advantages, data warehousing has also some issues, mainly regarding the time needed to perform the ETL process (which however occurs offline), and the domain knowledge required to correctly represent relationships among the integrated data. Furthermore, when original data sources are updated frequently, as it usually occurs for bioinformatics sources, the data in the warehouse become quickly obsolete; this demands to have in place suitable automatic procedures to regularly update easily the data in the warehouse. Additionally, due to the generally complex global data schema used, warehousing extension with the inclusion of new sources, or even maintenance against the evolution of the integrated sources, might be overwhelming, unless a modular and flexible data schema is adopted (Masseroli *et al.*, 2016).

Multiple bioinformatics systems based on the *data warehousing* approach have been and are being developed and actively used; some prominent examples are *EnsMart*, *Atlas*, *BioWarehouse*, *Biozon*, *GenoQuery*, and *GPKB*.

EnsMart (Kasprzyk *et al.*, 2004) is a generic data warehouse integrating and organizing data from individual databases into one query-optimized system for rapid and flexible querying of big biological data. It is based on the principle of creating a generic system from specific data sources, where disparate data can be integrated and interrogated in a flexible, efficient, unified, and domain-independent manner.

Fig. 2 Data warehousing data integration.

Atlas (Shah *et al.*, 2005) is a biological data warehouse that locally stores and integrates heterogeneous data (i.e., biological sequences, molecular interactions, homology information, functional annotations of genes, and biological ontologies) from multiple sources. It is based on individual relational data models for each of the integrated source data types, with data managed through Structured Query Language (SQL) calls implemented in a set of Application Programming Interfaces (APIs) for C++, Java, and Perl programming languages. These APIs include methods to parse and load source datasets into the Atlas database, and to facilitate data retrieval by offering end-users flexible, easy, integrated access to the data in the Atlas.

BioWarehouse (Lee *et al.*, 2006) is an evolving open source toolkit for constructing data warehouses; it combines different collections of bioinformatics databases within a single physical database management system (DBMS), in order to ease queries that span multiple databases. BioWarehouse aims to be a toolkit capable of supporting multiple alternative warehouses; its objective is to offer to every scientist the possibility to create a personal warehouse instance by combining different collections of databases. It also allows integrating local data with public bioinformatics sources in order to share experimental data with collaborators, or publish data online for the scientific community.

Biozon (Birkland and Yona, 2006) integrates multiple biological databases comprising heterogeneous types of biological data (e.g., DNA sequences, proteins, interactions and cellular pathways). Differently from other previous systems, besides warehousing existing data, it employs a single connected graph schema combined with a hierarchical ontology of data instances and relations; this allows computing and storing novel inferred data regarding similarity relationships and functional predictions of biological entities.

GenoQuery (Lemoine *et al.*, 2008) is a relational genomic warehouse adopting an original multi-tier architecture including a database layer and an entity layer; the latter one allows defining queries for searching instances of biological entities and their features in the distinct databases integrated in the warehouse, with no need of specifying in which original database search them.

The *Genomic and Proteomic Knowledge Base (GPKB)* (Masseroli *et al.*, 2016) employs a data warehouse approach to integrate a very high number of genomic and proteomic semantic annotations originally dispersed in many relevant sources (e.g., Entrez Gene, UniProt, IntAct, ExPASy Enzyme, GO, GOA, BioCyc, KEGG, Reactome, and OMIM). It innovatively adopts a flexible, modular, and multilevel global data schema founded on abstraction and generalization of the features of the data integrated; additionally, it implements several automatic processes supporting data integration and its maintenance, even when the integrated data sources evolve in number and structure besides content. These procedures also implement many techniques of data quality control to check the integrated data against a variety of possible errors and inconsistencies (Chisalberti *et al.*, 2010); thus, they avoid error propagation during their automatic processing, and guarantee consistency and quality of all integrated data, as well as their provenance tracking, which is a key factor for their subsequent proper processing and the interpretation of processing results. Furthermore, taking advantage of some defined logic rules and of the transitive relationships expressed by the biomolecular annotations integrated in the GPKB, novel annotations not existing in the integrated sources are automatically and reliably inferred and stored. Queries, although complex, can be easily expressed graphically on the knowledge base thanks to an intuitive Web interface, which also supports semantic query expansion and comprehensive explorative search of the integrated data, well supporting biomedical knowledge extraction.

The GPKB share with the TAMBS system the use of a model of knowledge in the world of bioinformatics and molecular biology; conversely, with the apparently similar BioWarehouse it shows several differences, mainly in the methodological choices about the global data schema adopted and the implemented data loading procedures. The GPKB data schema supports full data provenance tracking and is more flexible and easy to be expanded according the needs stemming from structural modifications of data sources previously integrated, or from the integration of new ones, which the implemented loading and updating procedures make easy.

Ontology-Based Data Integration

Proper integration of different data from multiple resources requires dealing with data heterogeneity, in order to effectively reconcile differences and recognize as equal, or referring to the same entity, data expressed in different ways. This is a complex task which involves recognizing the multiple different types of heterogeneities that can be present in the data and among their sources, and properly manage them.

While *system heterogeneity* refers to the use of different operating system and hardware platforms in distinct data sources, *structural heterogeneity* addresses the different structures where the data are stored in distinct data sources; in the case of using databases for data storing, the latter one refers to the different database models and/or schemas adopted. These heterogeneities are specifically dealt within each different data integration approach. On the other hand, *syntactic heterogeneity* concerns differences in the representation or format of the data, involving singular/plural and/or other lexical variations, which can be tackled using automatic natural language processing (NLP) techniques. Conversely, *semantic heterogeneity* involves differences in the interpretation of the meaning of the data, i.e., of the attributes of the data schema when data are stored in a database. Correctly managing and solving such heterogeneity requires the use of ontologies (i.e., formal models of representation with explicitly defined and named concepts and relationships linking them) able to consistently cover all the different concepts and the ways in which they are expressed in the integrated data (Lenzerini, 2002; Wache *et al.*, 2001).

In bioinformatics and computational biology, several relevant ontologies with high consistency and expressivity have been, or are being, developed, and they are widely adopted to express very numerous and publicly available annotations of multiple biological entities; this provides the ground to take advantage of such ontologies for ontology-based semantic integration of biological data and information which are usually sparsely stored. The most relevant of such ontologies are described in the following articles of this Encyclopedia.

Statistical and Network-Based Data Integration

When no logical, syntactic, lexical or semantic integration can be performed, advanced mathematical computational methods might be applied, particularly for the integration of numerical experimental results and of the information derived from them. Towards this goal, a variety of statistical univariate and multivariate techniques exists to identify variations or uniformities in datasets. However, traditional statistical methods have the limit of highlighting relationships among data only based on mathematical criteria (e.g., maximization of variance, or correlation), without taking into account correlations from biological origin. This suggests the combined use of different statistical and data mining techniques; the latter ones are available to discriminate groups of related data. They search for patterns in the data, usually returning several patterns which however include only a few significant ones. To automatically select them, novel pattern analysis methods are incorporated in existing data mining techniques, which are able to return a few results with a high likelihood of relevance.

Specific bioinformatics computational procedures, e.g., enrichment and pathway analyses, can be also used. They allow identifying biological entities that significantly share, or are related by, particular biological functions, on the basis of the information contained in public databases such as the Gene Ontology (GO) (Ashburner *et al.*, 2000) or the Kyoto Encyclopedia of Genes and Genomes (KEGG) (Ogata *et al.*, 1999). Pathway analyses can also help in capturing the interactions among biological entities that the data to be integrated describe. When this occurs, network-based analyses and visualizations can be adopted to support better biologically-driven data integration. In particular, depending on the type of interactions described, a biological network can be represented with different types of graphs (i.e., mathematical structures), including directed or undirected graphs, directed acyclic graphs (DAGs), trees, forests, minimum spanning trees, Boolean networks, and Steiner trees (Ma'ayan, 2011); these can be visualized using a variety of strategies to make graph layouts more informative.

Conclusion

To answer usually complex biomedical-molecular questions, which typically require to evaluate data of multiple types, integrative bioinformatics provides multiple approaches to integrate heterogeneous biomolecular and biomedical data that are increasingly produced and available in numerous different sources. Among the several different methods and implementations proposed towards this goal, the most used are *mediator-based* and *data warehousing* solutions. The former ones typically provide online integration of the distributed data needed to answer a given request, requiring only limited overhead efforts; thus, they are particularly useful when data to be integrated are small (although extracted from individual big datasets) and vary frequently, with requests that are variable and require the most updated data to be answered. Conversely, the latter ones require previous static integration of the originally distributed heterogeneous data, which are then comprehensively queried; such initial overhead, which in addition makes the integrated data to become potentially obsolete with respect to those in the original data sources, pays off when the integrated data must be comprehensively evaluated, particularly when such evaluation requires complex and time consuming processing. Other advanced integrative bioinformatics approaches more recently used include *ontology-based*, *statistical* and *network-based* data integration, which proved effective for better biologically-driven data integration.

Biographical Sketch

Marco Masseroli received the Laurea degree in Electronic Engineering in 1990 from Politecnico di Milano, Italy, and the PhD degree in Biomedical Engineering in 1996, from the Universidad de Granada, Spain. He is associate professor in the Dipartimento di Elettronica, Informazione e Bioingegneria at Politecnico di Milano, and lecturer of Bioinformatics and Biomedical Informatics. He carried out research activity in the application of Information Technology to the medical and biological sciences in several Italian and international research centers. He has also been visiting professor in the Departamento de Anatomia Patologica, Facultad de Medicina at the Universidad de Granada, Spain, and visiting faculty at the Cognitive Science Branch of the National Library of Medicine, National Institute of Health, Bethesda. His research interests are in the area of bioinformatics and biomedical informatics, focused on distributed Internet technologies, biomolecular databases, controlled biomedical terminologies and bio-ontologies to effectively retrieve, manage, analyze, and semantically integrate genomic information with patient clinical and high-throughput genetic data. He is the author of more than 170 scientific articles, which have appeared in international journals, books, and conference proceedings.

Integrative Bioinformatics of Transcriptome: Databases, Tools and Pipelines

Background

Recent findings clearly support the concept that interconnecting miRNAs with TF genes and other upstream regulators (URs) may be of major help for the elucidation of different biologic events including oncogenetic and disease progression (Afshar *et al.*, 2014). Accordingly, several novel approaches have been developed for the investigation of relations among miRNAs, expression of target genes and transcription factors (van Iterson *et al.*, 2013; Di Martino *et al.*, 2015). To this aim, traditional gene-set-enrichment tools (Huang *da et al.*, 2009) have been partially substituted by more sophisticated models based on a system-level or semantic-based analysis (Guzzi *et al.*, 2012; Schulz *et al.*, 2011), and data interpretation by the integration with prior biological knowledge, into the workflow of analysis, for example, the use of causal networks such as networks that explicitate the causal relationships (Felciano *et al.*, 2013; Catlett *et al.*, 2013). Based on the ability to retrieve the direction of interactions among genes (including mutual feed-forward loop), causal analysis is more efficient than classic enrichment methods (Guzzi *et al.*, 2015). Here, we discuss general concepts related to production of omic data, specifically of gene and miRNA expression data, then, we present main available platforms of analysis and discuss future improvements and challenges of databases integration.

mRNA, miRNA, and Transcription Factor Interactions

As stated by the central dogma of molecular biology, genes guide protein synthesis through mRNA molecules. Since the information contained in genes cannot be directly translated into proteins, information is at first transcribed into mRNA molecules. Each molecule of mRNA encodes the information for one protein. The mRNA molecules migrate through the nuclear envelope to the cytoplasm, where they are translated in proteins through the mechanism of the protein synthesis which includes other cellular RNAs such as rRNA of ribosomes and tRNA. Finally, each mRNA is translated into a polymer of amino acids: a protein. In an ideal case, the quantity of mRNA molecules should be directly related to the quantity of the related protein. In such a way, the investigation of the quantity of mRNA through for example microarray technology, should support the investigation of the quantity of produced proteins. Unfortunately, as suggested by experimental evidences, this process is made complex by the presence of regulatory mechanisms that directly influence the level of proteins. In particular, recent findings have elucidated the role of two main classes of molecules that influence positively and negatively the protein synthesis: miRNA and TF (Burgess, 2015).

miRNA refers to a set of small RNA molecules composed of 21–23 nucleotides that do not encode any protein but participate as regulators in protein formation (Bartel, 2004). Recent studies demonstrated that miRNAs play an essential role in carcinogenesis because the disgregation of their activity may cause the development of tumor invasion and migration (Calin and Croce, 2006). miRNAs also act as a possible new target for molecular target therapy of various cancers (Gallo Cantafio *et al.*, 2016; Di Martino *et al.*, 2016; Gulla *et al.*, 2016; Di Martino *et al.*, 2014, 2013) or as drugs (Misso *et al.*, 2014; Di Martino *et al.*, 2012; Morelli *et al.*, 2015). Thus, there is an increasing interest for miRNA studies in clinical applications such as in serological diagnosis and molecular-targeted therapeutics (Di Martino *et al.*, 2016; Tagliaferri *et al.*, 2012). On the other side, TFs are protein modulators that regulate gene transcription through binding to the promoter region of target genes by their DNA-binding domains. In such a way, TFs may increase gene expression and consequently protein levels. Recent evidences support the idea that interconnecting miRNAs with TF genes may better elucidate different biological events. Consequently, several novel approaches have been devoted to the investigation of relations among miRNAs, expression of target genes and TFs (van Iterson *et al.*, 2013). To this aim, traditional gene-set-enrichment tools (Huang *da et al.*, 2009). have been partially substituted by more sophisticated models based on a system-level or semantic-based analysis (Guzzi *et al.*, 2012).

Interaction Databases

The interaction databases here reported fall into three main classes:

- Databases storing associations among miRNA and genes, i.e., storing which genes are targeted by miRNAs.
- Databases storing the associations among TF and genes, i.e., storing which genes are targeted by TFs.
- Databases storing the associations among TF and miRNA, i.e., storing which TFs are targeted by miRNAs.

All of these databases may store both confirmed associations, associations supported by experimental evidences, and predicted associations, or associations that are predicted by computational methods. The current scenario presents some main characteristics: (i) the number of confirmed associations is in general less than that of predicted ones, (ii) the number of false positives (i.e., not real associations) is considerable, and (iii) the level of overlap among databases is low. Consequently, all the approaches consider different data sources and integrate them in order to enhance the quality of considered associations.

The association among miRNAs and their target genes, for instance, genes up- or down-regulated, is currently an increasing research area. Currently, there exist different prediction software, that can predict possible genes regulated by a miRNA through machine learning approaches, and different technological platforms that are able to confirm these results in wet lab experiment (Rajewsky, 2006). As a result of the joint effort between both in silico and wet lab experiments, are now available several databases that store the association among miRNAs and mRNAs, such as Microcosm (Griffiths-Jones *et al.*, 2008), microRNA.org (Betel *et al.*, 2008), DIANA-microT (Maragkakis *et al.*, 2009), miRDB (Wang, 2008), PicTar (Krek *et al.*, 2005), PITA (Kertesz *et al.*, 2007), RNA22 (Miranda *et al.*, 2006), and TargetScan (Grimson *et al.*, 2007).

Similar to miRNAs, the complete enumeration of all the interactions among TF and genes is far to be complete. Thus, information stored into databases is quite incomplete. Main experiments used for discovering TF-gene relations are immunoprecipitations (ChIP) followed by sequencing (ChIP-seq) or by microarray hybridization (ChIP-chip) (Buck and Lieb, 2004). Both techniques enable a high-throughput discovery of relations, but usually, they also generate a large number of false positives (Qin *et al.*, 2011). In parallel to these techniques, we should recall main computational approaches for predicting TF and for retrieving resulting information from databases. For instance, the TRANSFAC database (Wingender, 2008) is one of the main resources of experimentally verified TF targets from publications or databases. Similarly, ChEA (Lachmann *et al.*, 2010), stores ChIP-seq and ChIP-chip data related to TF targets generated by different projects. The availability of different data sources with different reliabilities causes the need of integration of several of these methods and data to obtain comprehensive and accurate TF targets (Chen and Rajewsky, 2007).

The third main knowledge source is represented by databases storing information related to the regulation of miRNAs by TFs. The number of TF-miRNA regulation databases is lower than the number of the other two kinds of databases, because this approach is the youngest area of research. Examples of databases are TransmiR (Wang *et al.*, 2010), TransFac (Lenhard and Wasserman, 2002), TargetScan (Agarwal *et al.*, 2015), and PicTar (Krek *et al.*, 2005).

Tools and Pipelines

Here we report current available tools for integrative analysis approaches.

dChip-GemiNi (Gene and miRNA Network-Based Integration)

dChip-GemiNi (Gene and miRNA Network-based Integration) is a web server freely available for academic users which is able to integrate and analyze paired miRNA-mRNA expression data. The server side is written using the R programming language. Users may also download the source code for running it in a local environment. The ability of dChip-GemiNi has been tested by using some paired miRNA-mRNA datasets of solid cancers (liver, kidney, prostate, lung, and germ cell), and results are discussed in the paper of Yan *et al.* (2012).

The workflow of analysis that has been used to build dChip-GemiNi contains four steps:

1. First, publicly available databases as TargetScan for miRNA-mRNA association and TRANSFAC for TF binding sites) have been used to construct TF-miRNA-gene networks. Specifically, networks in which nodes are miRNA, genes, and TF, and edges represent the regulates relationship among them (e.g., a miRNA is connected to the target genes and a TF is connected to the target genes).
2. Then, experimental data including gene and miRNA expression profiles were collected from publicly databases (e.g., GEO).
3. Resulting networks (obtained in steps 1 and 2) were mined to extract significant motifs referred to as FFL motifs by small connected graphs in which there exist three different nodes (TF, miRNA, and mRNA).
4. Data managed in step 1 were used to further validate the statistical relevance of results through an ad hoc defined network motif score (NMS). The NMS is a function of multiple scores, including TF and miRNA binding scores to their target sequences, differential expression *P* values of the FFL components between normal and cancer tissues, and TF and miRNA's target enrichment in differentially expressed genes and miRNAs.

The workflow of analysis start from collection of experimental data, then two vectors of expression levels (one for mRNA and one for miRNA) are obtained from wet lab by analyzing two conditions, for instance, normal and cancer. Data may be paired as for sample, where were collected both mRNA and miRNA data for each sample, or unpaired such as for data belong to the same class but not to the same sample. Data are uploaded into the web server (see Relevant Websites section) so that an output of a list with significant FFLs, that are altered with respect to those used as the null model, will obtained. dChip-GemiNi is also able to individuate FFLs consisting of TFs (i.e., genes that are able to regulate the expression of other genes), miRNAs, and their common target genes. In such a way, new knowledge can be provided that is challenging to be discovered by the classical analysis. Experimental data are compared with respect to known associations among miRNAs, mRNAs, and TFs obtained from the literature and stored into the web server. TFs derived from literature are used as a null model to statistically rank predicted FFLs from the experimental data.

MAGIA2

MAGIA2 (Bisognin *et al.*, 2012), is the evolution of the MAGIA web tool for the integrated analysis of both genes and microRNA. MAGIA2 is deployed as a freely available web server (see Relevant Websites section). To build association networks, MAGIA2 uses

eight different databases of miRNA/mRNA associations: Microcosm (Griffiths-Jones *et al.*, 2008), mirna.org (Betel *et al.*, 2008), DIANA-microT (Maragkakis *et al.*, 2009), miRDB (Bisognin *et al.*, 2012), PicTar (Miranda *et al.*, 2006), PITA (Kertesz *et al.*, 2007), RNA22 (Miranda *et al.*, 2006), and TargetScan (Grimson *et al.*, 2007). Such predictors are used to build the null models, i.e., associations that are known by literature. Regarding TFs, MAGIA2 uses experimentally validated TF-miRNA interactions reported in mirGen2 (Alexiou *et al.*, 2010) and TransmiR (Wang *et al.*, 2010), whereas TF-gene interactions are obtained from ECRbase database (Loots and Ovcharenko, 2007).

The analysis through the MAGIA2 web server starts by uploading data, usually by the use of matrix for gene/transcripts and one for miRNA expression data. Data may belong to time series experiments in which for each sample there exists a pair miRNA/mRNA experiment (referred to as matched data), or a two-class experiment (referred to as un-matched data). Then, users select an association measure among mRNA and miRNA, i.e., a measure of relatedness among expression values. For matched experiments, MAGIA2 offers the following measures: Pearson linear correlation, Spearman rank-based correlation, and an association measure based on information theory for time series experiments (referred to as matched). Diversely, for un-matched design, only a meta-analysis is possible.

The choice among measures is strictly dependent on the characteristics of data: for non-normally distributed data and/or small sample size experiments (3–5), it is suggested to use Spearman correlation, which is a non-parametric rank-based linear measure, whereas for normally distributed data and medium-large sample size (more than 5), authors suggest the use of the Pearson linear correlation measure; finally, for large sample size (more than 20), it is suggested to use mutual information that is an information measure quantifying the mutual dependence of variables.

Conversely, for un-matched experiments, that are experiments in which samples are subdivided into two classes, the web server offers the meta-analysis approach that is based on the combination of *P values* of differential expression, distinctly for genes and miRNAs, across sample classes. The user may also choose which databases are used to extract associations from those explained so far. In case of choice of multiple databases, search results may contain their union or intersection. Finally, experimentally derived associations are compared to those contained in the databases.

mirConnX

mirConnX (Huang *et al.*, 2011) is based on a broader perspective with respect to the previous approaches since it uses a genome-wide approach. Unfortunately, it enables only the analysis of data of two organisms: human and mouse. The workflow of analysis is based on the comparison of two networks of associations among genes, TFs, and mRNAs.

The first network is used as a null model and is derived from the analysis of databases and literature. In this network, nodes are miRNAs, TFs, and genes, and edge connects two nodes when an association has been found. Examples of associations are a miRNA that regulates a gene or a TF, or a TF that regulates a gene. Edges are weighted, and the weight reflects the strength of the association. miRNA targets are derived by integrating results stored in PITA (Kertesz *et al.*, 2007), miRANDA (Enright *et al.*, 2003), TargetScan (Grimson *et al.*, 2007), RNAhybrid (Kruger and Rehmsmeier, 2006), Pictar (Krek *et al.*, 2005), TarBase (Papadopoulos *et al.*, 2009) and miRecords (Xiao *et al.*, 2009) databases. Similarly, associations among TF and genes are derived by integrating predictions stored in JASPAR (Xie *et al.*, 2005) and TRANSFAC (Wingender, 2008). The integration step is based on a mathematical model which is able to derive a value of confidence for each prediction that is used as a weight for the resulting edge. The network built from experimental data is obtained by analyzing all the possible pairwise interactions between TFs, miRNAs, and genes across the samples/replicates. The user may choose different measures of associations, both parametric and non-parametric, such as Pearson, Spearman, and Kendall.

Finally, the software integrates the two networks via a simple weighted sum function (*S*) producing a novel network in which edges, which are found in both networks, have a greater weight. Results are finally visualized by using a Cytoscape-based interface (Smoot *et al.*, 2011) and all feed-forward loops, and their neighbors are evidenced. In addition, other simple analyses can be executed including the ontology-based analysis.

IntegraMiR

IntegraMiR (Afshar *et al.*, 2014) is a novel approach of integration of data that is based on the workflow. It receives as input mRNA and miRNA expression data, obtained from samples that are subdivided into two classes (e.g., controls vs. cases). It starts by searching for differentially expressed genes and mRNAs between two conditions by using the Bioconductor package LIMMA (Smyth, 2005). This step produces two lists, one for differentially expressed genes and one for differentially expressed miRNAs. Moreover, IntegraMiR uses LIMMA package to perform gene set enrichment analysis (GSEA), taking into account known biological knowledge about these transcripts with the aim to derive biological significance of both changed and unchanged transcripts expression. Then, associations among mRNA and miRNA are derived considering their individual expression levels (i.e., considering pairs of mRNA-miRNA whose regulation is inversely correlated) or through their target interactions – via functional analysis through literature and databases. At the end of this step, IntegraMiR uses the TRANSFAC database (Wingender, 2008) to derive associations among TFs and mRNAs and the TransmiR database (Papadopoulos *et al.*, 2009) to derive associations among TFs and miRNAs. In particular, TransmiR focuses only on differentially expressed miRNA and mRNA. Thus, it can reconstruct FFLs whose members are differentially expressed. These FFLs are then organized considering the kind of deregulation and ranked by

using a statistical approach and visualized to the user (see the original publication for a complete list of results). The software is available for download (Afshar *et al.*, 2014).

Conclusions

As evidenced before, the TF-miRNA-mRNA association represents undoubtedly a main resource for elucidating gene expression regulation at a systems level. The complete determination of miRNA and TF targets will enable a more powerful and reliable analysis. Consequently, from a computational point of view, the integration of more data sources may improve the quality of analysis, since computational TF-miRNA regulatory networks are available for some genomes and diseases. Moreover, integrating TF-miRNA regulatory networks with other networks will aid in explaining how these networks regulate the biological processes and diseases at the systems level.

Biographical Sketch

Maria Teresa Di Martino, is lab assistant professor in modern technologies development at Magna Graecia University and Biologist at Medical Oncology and Translational Medical Oncology Units of Catanzaro Medical School. She had degree in Biological Science at University of Catania, Italy and the Speciality degree in clinical biochemistry and molecular biology at Medical School of Catanzaro. She worked as researcher at Biotechnology section of Agriculture Industrial Development, then moved at Catanzaro University, Clinical Chemistry Unit and Neonatal Screening, as diagnostic-clinical staff. After, the experience of guest researcher at Jerome Lipper Multiple Myeloma Center, Dana-Farber Cancer Institute and Harvard Medical School, Boston, She works at Magna Graecia University as diagnostic-clinical staff of Medical Oncology Units and as translational oncology investigator of Laboratory of Molecular Profiling and modern technologies development with main focus in innovative therapeutics. To this aim is actively pursued the application of computational strategies to analyze and integrate omic data to gain novel information in the molecular architecture of the cancer disease and derive novel biomarkers and new technological tools clinical translation. Recent researches focus on the development of preclinical models of multiple myeloma for the study of therapies based on miRNA mimics or inhibitors. Lastly, she develops experimental platform for research in pharmacogenomic profiling in order to test chemiotherapeutic toxicity and to identify biomarkers for toxicity prevention in different human cancers and in rare diseases.

Introduction

In recent years, researchers are increasing their interest in applying data management techniques for information extraction from life related data sources. Information extraction is referred to the analysis of knowledge from several sources in order to understand the dynamics in life related processes, such as biological functions, environmental information, humans-environment relations. Usually, data are in raw format with heterogeneous structures; thus, a preprocessing phase is often performed to make the data usable to algorithms and tools (Belkin and Ingwersen, 2008), as well as to make them context-specific for the field of interest (Quan, 2007). This allows to extract knowledge from raw information (Bawden and Robinson, 2009), as well as to design data structures able to host biological related data (Nelson, 1994). Data can be collected in an Information Retrieval (IR) system; it is able to offer solutions for data integration of heterogeneous collections of data (Christopher *et al.*, 2008). Generally, it implements three main modules:

- indexing: that collects sets of concepts to generate a summary related to stored information,
- classification: used to relate information to indexes mechanisms,
- querying: used for information extraction through filtering, as well as keywords searching.

The indexation and the querying are often expressed using a syntax consisting of keywords through a key-value association. IR systems allow also to integrate data coming from different data sources, and thus heterogeneous both in format and structure (Stevens *et al.*, 2000). Data-Integration techniques are used to handle heterogeneous resources (e.g., physiology, pharmacology, and clinical data). IR can be enriched by ontologies; i.e., in Livingston *et al.* (2015) data is used for instance to correlate terms and concepts in life sciences. Ontologies can be used to enrich an existing set of data in order to build a relational model that allows an user to retrieve information of interest using query lang; e.g., Wild *et al.* (2012) uses SPARQL, a query language for graph based data. The semantics analysis of biomedical data is required to integrate information from sources with different schemes; an example may be related to the ontological databases, such as: SNOMED CT (Clinical Terms), International Classification of Disease (ICD) 9 and ICD-10, and Human Phenotype Ontology (HPO).

This article presents an overview of solutions used in life science to retrieve knowledge, as well as methods and algorithms for data analysis and integration based on machine-learning and data-mining techniques.

Data in Life Science

In life science, as well as in genomic and more generally in biomedicine, the data heterogeneity is growing in conjunction with analysis technologies that consequently produce output greatly diversified; think to the different technologies used to acquire data in high-throughput or micro-array experiments, such as: gene expression, single nucleotide polymorphisms (SNPs), copy number variation (CNV), proteomic and protein-protein interactions. All data need to be store using a model specific to the type of information that must be contained in it, and represented by a specific file format. An algorithm takes the advantage of each format to better process the input data and analyze them; generally, in life sciences the models are based on a key-value form. Several formats, with the related data models, are available for storage information in efficient way. Biomedical resources are often stored using flat file formats, such as: OWL, OBO, RDF, and CSV. These models stores the information using plain text; for instance, (i) in a CSV it consisting in tabular data where each line is a record that contains one or more values, (ii) in a OWL it consisting in classes of objects that describe taxonomies and classification networks. An ontology is a formal representation that defines a set of types, properties and interrelationships between the entities in a defined domain; furthermore, this terminology concerns a set of concepts that may be used to describe knowledge. An ontology may be of 'high level' or 'specific domain': the former is constituted by concepts that organize the upper parts of a knowledge base; instead, the latter may range in all the fields where syntax and semantics are permitted. Currently, most of the important biological ontologies use the OBO format representation. In Tirmizi *et al.* (2011) a methodology for translating OBO ontologies to OWL using the organization of the Semantic Web is presented. This solution produces an OWL Description Logics (DL) subset in order to improve the computational properties for efficiency and correctness. OWL is a Semantic Web language that supports query languages, and distributed infrastructure for information interchange; it is maintained by the World Wide Web consortium (W3C). In this scenario, the data integration techniques and ontologies can be used to perform a correlation between concepts and heterogeneous resources. Gene Ontology (GO) (Ashburner *et al.*, 2000) is a biological ontology used to retrieve information represented by terms consisting of: molecular functions, biological processes, and subcellular localizations. Analogously, Disease Ontology (DO) (DO Official WebSite, 2016) correlates human diseases through the cross-mapping of medical vocabularies (e.g., MeSH, ICD, NCI Thesaurus, SNOMED and OMIM); it contains several information consisting of genetic variations, phenotypes, proteins, and drugs. Generally, an ontology is used to retrieve additional information related to its

Fig. 1 FASTQ format.

content; it is modeled using taxonomies that represent, for instance, a genes list with the relations for each one (e.g., in Gene Ontology), or the definitions for a disease (e.g., Disease Ontology). Using data-integration methods a scientist can join this information in order to retrieve the molecular functions and its relations in biological processes. Furthermore, bioinformatics focuses its attention on life sciences related data in order to analyze the role of proteins, genes biological processes, and their functions for preventing and treating of diseases. Generally, in genomics the information (e.g., genes, nucleotide variations, biological sequences) are acquired using Microarray and Next Generation Sequencing (NGS) technologies, and subsequently processed by bioinformatics algorithms. A common file format is FASTQ, that is generally used as input for the alignment processes. FASTQ is composed of textual strings representing the gene sequences; it is composed by three main parts: (i) the first line begins with a '@' character followed by a Sequence ID and an optional description; (ii) the second is a long string characterized by symbols which denote the gene sequence; (iii) the latter represents the quality score for the sequence, its value is encoded using the American Standard Code for Information Interchange (ASCII). The sequence and its related quality score have the same length. Generally, between the second and third line a '+' char (optionally followed by the same Sequence ID) is also added to break the gene sequence content from the score; **Fig. 1** shows a summary model for the FASTQ format.

Techniques and Methods

A case study in data analysis for life sciences can be represented by a workflow which includes the following steps: (i) data retrieval from remote sources; (ii) heterogeneous data storage for local analysis in order to improve the performance and time consuming; (iii) heterogeneous resource modeling and indexation; (iv) knowledge extraction; optionally, (v) querying and (vi) statistical analysis. **Fig. 2** shown a diagram for the workflow.

Assuming that we want to integrate several 'omics information in order to combine large-scale biological data or to retrieve important biological insights, an algorithm for the multivariate analysis (Rohart *et al.*, 2017) of biological datasets could be implemented. Other approaches concern the ontology-based information systems for biomedicine which using semantic interoperability of biomedical resources in order to allow the storage and the querying of medical data. For instance, we can use the ontologies for knowledge management linking the terms related to: concepts, processes, and methods; similarly, in Jurisica *et al.* (2004) this approach was implemented using Data-integration and Semantic Similarity techniques in order to solve conflicts in heterogeneous data, as well as to map information on a formal schema. Furthermore, a Decision Support System (DSS) can be implemented to extract and analyze information from a large amount of data stored in a database; the latter could be based on a relation model using a Relational Database Management System (RDBMS). Assuming that we want to increase the effectiveness for an analysis a DSS could be used to provide a plan during a management activity through a Strategic Decisions-Making process. For instance, a similar approach is used in Cinaglia *et al.* (2015) to get an immediate online feedback from expert specialists, as well as to allow remote analysis of electrocardiogram (ECG). Generally, in clinical applications a DSS is implemented using Machine Learning (ML) techniques to support the identification of complex patterns through a multivariate statistical analysis, as well as to predict information using the knowledge extracted from larger dataset (Crippa *et al.*, 2017). In this scenario, a pattern can be represented as a sequence of items that can be modeled using a mathematical function. In a biological image a pattern is represented from a subset of numbers organized in a matrix; for instance if you're going to do a study in neurosciences, a pattern could be identified through an algorithm for pattern-recognition which integrates data across multiple variables in order to detect the alterations in brain's functionalities, as well as to investigate the regularities in the data using ML techniques. An ML algorithm can be performed using a training-set of known patterns (supervised learning), or it can be used to analyze directly an input dataset when no label was previously set (unsupervised learning) in order to discover unknown patterns during the prediction. Assuming that a physician needs to integrate several neuroimaging datasets for knowledge extraction, a virtual data-integrator could be implemented. Assuming that a study on the schizophrenia is being conducted, it could be used to retrieve data from remote sources (e.g., the datasets in input could

Fig. 2 Data in life sciences: Summary workflow.

be: HID, MRN's Collaborative Imaging and Neuroinformatics System, and XNAT) for a local analysis that integrates the information; this approach is used in SchizConnect (Ambite *et al.*, 2015; Wang *et al.*, 2016) where a query engine is also implemented, using an OGSA-DAI/DQP architecture (OGSA: Open Grid Services Architecture; DAI: Distributed Access and Integration; DQP: Distributed Query Processing), to offer a streaming data-flow evaluation engine and a distributed query engine.

Algorithms

In bioinformatics, data-mining and machine-learning solutions allow a scientist to obtain an interdisciplinary view from heterogeneous resources. Assuming that we want acquire information from ontological resources, an algorithm can be implemented to perform biological data analysis and integration. Briefly, it could be used for the management and integration of heterogeneous data acquired from ontological resources, such as: Disease Ontology, Gene Ontology, and DisGenet. For instance, we can imagine that a physician needs to retrieve additional informations for a disease using the ontologies. Thus, during the data-integration analysis the algorithm performs a pipeline composed from two phases. The first concerns the preprocessing: the data are integrated and organized in a single structure retrieving the information from the ontological datasets. Using this approach, the algorithm models a local ontology where novel relations among the concepts are established.

In Fig. 3 a diagram for the first phase is reported: Gene Ontology and Disease Ontology (OBO File Format) can be described as a Graph, where each Gene/Disease is a node that contains metadata (biological and descriptive information); DisGeNet (Pinero *et al.*, 2015) (TSV File Format) is described using a Tabular Structure (Cinaglia *et al.*, 2017).

The second phase consists in the analysis: when an user performs a request, the local data are investigated in order to return the information of interest. The Fig. 4 shows a possible output that concerns the genes involved for the disease, as well as the meta-data for each gene founded (e.g., description, biological function, biological processes and relations with other genes).

Similarly, in Cinaglia *et al.* (2017) an ontology-based system for clinical data integration and analysis is implemented. The literature presents several solutions to perform data analysis using the correlation between clinical ontologies and biological information.

Assuming that we want implement an algorithm for Hierarchical Hyperbolic SOM (H2SOM) clustering we needs to combine more features related to principles of machine learning and scientific-information in order to analyze the aspects of Toponome Imaging System (TIS) images in terms of space and collocation. This solution is able to resolve non-linear features (e.g., using dynamic interactive manipulation of the colors) and to organize clusters in a hierarchical structure; a similar approach is developer in Kolling *et al.* (2012). In a general-purpose case a toolkit can be used to speed up the algorithm implementation; for instance, Scikit-Learn (Pedregosa *et al.*, 2011) is a general purpose machine learning toolkit (based on Numpy and SciPy) to solve complex data analysis tasks in order to simplify the implementation of tool in Bioinformatics. Using NumPy and SciPy, a bioinformatics scientist is able to implement an algorithm for storage and manipulation of multi-dimensional array, as well as for the implementation of data structure and mathematical functions. During the implementation several Machine Learning approaches can be combined to improve the data analysis; for instance, in Abraham *et al.* (2014) supervised and unsupervised learning approaches are used to extract knowledge during neurological analysis.

Fig. 4 Data-integration analysis: Output.

The handling and manipulation of bioimaging data is required during the identification of patterns and features in order to check the presences of tumors or pathologies. A popular tool for medical image analysis is 3DSlicer (Kikinis *et al.*, 2014) (supported by the National Institutes of Health); it is used in research community to perform segmentation algorithms, ranging in complexity and automation.

Conclusions and Additional Reading

In life science the new analysis technologies produce a high amount of data that needs to be analyzed in order to extract knowledge; in this context, the bioinformatics helps to overcome compatibility issues due to the greatly diversification of the data models and types in order to obtain an interdisciplinary view. Data integration techniques, Machine-learning algorithms, as well as the data-mining approaches can be used to perform a correlation between the concepts within heterogeneous resources. An

overview for the techniques and methods for data retrieval in life sciences is presented, as well as the bioinformatics algorithms and tools for knowledge extractions with references to the data models and their structures.

Biographical Sketch

Pietro Cinaglia is PhD Student in Bioinformatics applied to Neurosciences at University of Catanzaro, Italy. His research activity concerns the study of Bioimaging and Bioinformatics solutions in Neurosciences, as well as the development and implementation of algorithms for biomedical data analysis and integration. He received his master degree cum laude in Biomedical Engineering at University of Catanzaro. From 2014–2016 he worked as software engineer at Magna Graecia of Catanzaro in several research projects.

Domenico Mirarchi is PhD Student of Magna Graecia University of Catanzaro since 2015. In 2014 worked as a research fellow at Magna Graecia University of Catanzaro on a “smart cities” project. During this period he has been involved in the design and implementation of algorithms. He received his master degree in 2011 in Biomedical Engineer.

Pierangelo Veltri is an associate professor in Computer Science at the Magna Graecia University of Catanzaro, Italy. He obtained his PhD in Computer Science from the University of Orsay (Paris XI), where he was researcher until 2002. He was researcher at INRIA, Pars from 1998 to 2002. From 2002–2012 was Assistant Professor in computer science and bioinformatics, and from 2012 Associate Professor.

EDITORS IN CHIEF

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. She hosted the Macquarie Node of the ARC Centre of Excellence in Bioinformatics (2008–2013). She was elected the first Australian Board Director of the International Society for Computational Biology (ISCB; 2003–2005); President of Asia-Pacific Bioinformatics Network (2005–2016) and Steering Committee Member (2007–2012) of Bioinformatics Australia. She initiated the Workshops on Education in Bioinformatics (WEB) as an ISMB2001 Special Interest Group meeting and also served as Chair of ICSB's Education Committee. Shoba currently serves as Co-Chair of the Computational Mass Spectrometry (CompMS) initiative of the Human Proteome Organization (HuPO), ISCB and Metabolomics Society and as Board Director, APBioNet Ltd.

Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books as well as articles for the 2013 Encyclopedia of Systems Biology. She is currently an Editor-in-Chief of the Encyclopedia of Bioinformatics and

Computational Biology and the Bioinformatics Section Editor of the Reference Module in Life Science as well as an editorial board member of several bioinformatics journals.

Dr. Gribskov graduated from Oregon State University in 1979 with a Bachelors of Science degree (with Honors) in Biochemistry and Biophysics. He then moved to the University of Wisconsin-Madison for graduate studies focused on the structure and function of the sigma subunit of *E. coli* RNA polymerase, receiving his Ph.D. in 1985. Dr. Gribskov studied X-ray crystallography as an American Cancer Society post-doctoral fellow at UCLA in the laboratory of David Eisenberg, and followed this with both crystallographic and computational studies at the National Cancer Institute. In 1992, Dr. Gribskov moved to the San Diego Supercomputer Center at the University of California, San Diego where he was lead scientist in the area of computational biology and an adjunct associate professor in the department of Biology. From 2003 to 2007, Dr. Gribskov was the president of the International Society for Computational Biology, the largest professional society devoted to bioinformatics and computational biology. In 2004, Dr. Gribskov moved to Purdue University where he holds an appointment as a full professor in the Biological Sciences and Computer Science departments (by courtesy). Dr. Gribskov's interests include genomic and transcriptomic analysis of model and non-model

organisms, the application of pattern recognition and machine learning techniques to biomolecules, the design and implementation of biological databases to support molecular and systems biology, development of methods to study RNA structural patterns, and systems biology studies of human disease.

Kenta Nakai received the PhD degree on the prediction of subcellular localization sites of proteins from Kyoto University in 1992. From 1989, he has worked at Kyoto University, National Institute of Basic Biology, and Osaka University. From 1999 to 2003, he was an Associate Professor at the Human Genome Center, the Institute of Medical Science, the University of Tokyo, Japan. Since 2003, he has been a full Professor at the same institute. His main research interest is to develop computational ways for interpreting biological information, especially that of transcriptional regulation, from genome sequence data. He has published more than 150 papers, some of which have been cited more than 1,000 times.

Christian Schönbach is currently Department Chair and Professor at Department of Biology, School of Science and Technology, Nazarbayev University, Kazakhstan and Visiting Professor at International Research Center for Medical Sciences at Kumamoto University, Japan. He is a bioinformatics practitioner interfacing genetics, immunology and informatics conducting research on major histocompatibility complex, immune responses following virus infection, biomedical knowledge discovery, peroxisomal diseases, and autism spectrum disorder that resulted in more than 80 publications. His previous academic appointments included Professor at Kumamoto University (2016–2017), Nazarbayev University (2013–2016), Kazakhstan, Kyushu Institute of Technology (2009–2013) Japan, Associate Professor at Nanyang Technological University (2006–2009), Singapore, and Team Leader at RIKEN Genomic Sciences Center (2002–2006), Japan. Other prior positions included Principal Investigator at Kent Ridge Digital Labs, Singapore and Research Scientist at Chugai Institute for Molecular Medicine, Inc., Japan. In 2018 he became a member of International Society for Computational Biology (ISCB) Board of Directors. Since 2010 he is serving Asia-Pacific Bioinformatics Network (APBioNet) as Vice-President (Conferences 2010–2016) and President (2016–2018).

VOLUME EDITORS

Mario Cannataro is a Full Professor of Computer Engineering and Bioinformatics at University “Magna Graecia” of Catanzaro, Italy. He is the director of the Data Analytics research center and the chair of the Bioinformatics Laboratory at University “Magna Graecia” of Catanzaro. His current research interests include bioinformatics, medical informatics, data analytics, parallel and distributed computing. He is a Member of the editorial boards of Briefings in Bioinformatics, High-Throughput, Encyclopedia of Bioinformatics and Computational Biology, Encyclopedia of Systems Biology. He was guest editor of several special issues on bioinformatics and he is serving as a program committee member of several conferences. He published three books and more than 200 papers in international journals and conference proceedings. Prof. Cannataro is a Senior Member of IEEE, ACM and BITS, and a member of the Board of Directors for ACM SIGBIO.

Bruno Gaeta is Senior Lecturer and Director of Studies in Bioinformatics in the School of Computer Science and Engineering at UNSW Australia. His research interests cover multiple areas of bioinformatics including gene regulation and protein structure, currently with a focus on the immune system, antibody genes and the generation of antibody diversity. He is a pioneer of bioinformatics education and has trained thousands of biologists and trainee bioinformaticians in the use of computational tools for biological research through courses, workshops as well as a book series. He has worked both in academia and in the bioinformatics industry, and currently coordinates the largest bioinformatics undergraduate program in Australia.

Mohammad Asif Khan, PhD, is an associate professor and the Dean of the School of Data Sciences, as well as the Director of the Centre for Bioinformatics at Perdana University, Malaysia. He is also a visiting scientist at the Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine (JHUSOM), USA. His research interests are in the area of biological data warehousing and applications of bioinformatics to the study of immune responses, vaccines, inhibitory drugs, venom toxins, and disease biomarkers. He has published in these areas, been involved in the development of several novel bioinformatics methodologies, tools, and specialized databases, and currently has three patent applications granted. He has also led the curriculum development of a Postgraduate Diploma in Bioinformatics programme and an MSc (Bioinformatics) programme at Perdana University. He is an elected ExCo member of the Asia-Pacific Bioinformatics Network (APBioNET) since 2010 and is currently the President of Association for Medical and Bio-Informatics, Singapore (AMBIS). He has donned various important roles in the organization of many local and international bioinformatics conferences, meetings and workshops.

PREFACE

Bioinformatics and Computational Biology (BCB) combine elements of computer science, information technology, mathematics, statistics, and biotechnology, providing the methodology and *in silico* solutions to mine biological data and processes, for knowledge discovery. In the era of molecular diagnostics, targeted drug design and Big Data for personalized or even precision medicine, computational methods for data analysis are essential for biochemistry, biology, biotechnology, pharmacology, biomedical science, and mathematics and statistics. Bioinformatics and Computational Biology are essential for making sense of the molecular data from many modern high-throughput studies of mice and men, as well as key model organisms and pathogens. This Encyclopedia spans basics to cutting-edge methodologies, authored by leaders in the field, providing an invaluable resource to students as well as scientists, in academia and research institutes as well as biotechnology, biomedical and pharmaceutical industries.

Navigating the maze of confusing and often contradictory jargon combined with a plethora of software tools is often confusing for students and researchers alike. This comprehensive and unique resource provides up-to-date theory and application content to address molecular data analysis requirements, with precise definition of terminology, and lucid explanations by experts.

No single authoritative entity exists in this area, providing a comprehensive definition of the myriad of computer science, information technology, mathematics, statistics, and biotechnology terms used by scientists working in bioinformatics and computational biology. Current books available in this area as well as existing publications address parts of a problem or provide chapters on the topic, essentially addressing practicing bioinformaticists or computational biologists. Newcomers to this area depend on Google searches leading to published literature as well as several textbooks, to collect the relevant information.

Although curricula have been developed for Bioinformatics education for two decades now (Altman, 1998), offering education in bioinformatics continues to remain challenging from the multidisciplinary perspective, and is perhaps an NP-hard problem (Ranganathan, 2005). A minimum Bioinformatics skill set for university graduates has been suggested (Tan *et al.*, 2009). The Bioinformatics section of the Reference Module in Life Sciences (Ranganathan, 2017) commenced by addressing the paucity of a comprehensive reference book, leading to the development of this Encyclopedia. This compilation aims to fill the “gap” for readers with succinct and authoritative descriptions of current and cutting-edge bioinformatics areas, supplemented with the theoretical concepts underpinning these topics.

This Encyclopedia comprises three sections, covering Methods, Topics and Applications. The theoretical methodology underpinning BCB are described in the Methods section, with Topics covering traditional areas such as phylogeny, as well as more recent areas such as translational bioinformatics, cheminformatics and computational systems biology. Additionally, Applications will provide guidance for commonly asked “how to” questions on scientific areas described in the Topics section, using the methodology set out in the Methods section. Throughout this Encyclopedia, we have endeavored to keep the content as lucid as possible, making the text “... as simple as possible, but not simpler,” attributed to Albert Einstein. Comprehensive chapters provide overviews while details are provided by shorter, encyclopedic chapters.

During the planning phase of this Encyclopedia, the encouragement of Elsevier’s Priscilla Braglia and the constructive comments from no less than ten reviewers lead our small preliminary editorial team (Christian Schönbach, Kenta Nakai and myself) to embark on this massive project. We then welcomed one more Editor-in-Chief, Michael Gribskov and three section editors, Mario Cannataro, Bruno Gaeta and Asif Khan, whose toils have results in gathering most of the current content, with all editors reviewing the submissions. Throughout the production phase, we have received invaluable support and guidance as well as milestone reminders from Paula Davies, for which we remain extremely grateful.

Finally we would like to acknowledge all our authors, from around the world, who dedicated their valuable time to share their knowledge and expertise to provide educational guidance for our readers, as well as leave a lasting legacy of their work.

We hope the readers will enjoy this Encyclopedia as much as the editorial team have, in compiling this as an ABC of bioinformatics, suitable for naïve as well as experienced scientists and as an essential reference and invaluable teaching guide for students, post-doctoral scientists, senior scientists, academics in universities and research institutes as well as pharmaceutical, biomedical and biotechnological industries. Nobel laureate Walter Gilbert predicted in 1990 that “In the year 2020 you will be able to go into the drug store, have your DNA sequence read in an hour or so, and given back to you on a compact disk so you can analyze it.” While technology may have already arrived at this milestone, we are confident one of the readers of this Encyclopedia will be ready to extract valuable biological data by computational analysis, resulting in biomedical and therapeutic solutions, using bioinformatics to “measure” health for early diagnosis of “disease.”

Background and Context

Up until the 1990s, data generated in biological and biomedical research were mostly shared via research articles. The development and democratisation of computers, on one hand, as well as the creation of network of this informatics infrastructure, on the other, opened a completely new way to share information and provided new possibilities to structure and integrate data that free text research articles cannot achieve. Concomitantly, high throughput technologies with applications for the biomedical sciences started to emerge, which allowed to analyze large numbers of biological samples (for example, microarrays) and to sequence ever larger and longer nucleic acid sequences (DNA and RNA). This gave rise to the new fields of proteomics, genomics, and transcriptomics. Repositories storing this data have been growing at exponential rates. One of the most important sequence repositories, GenBank, contains nucleotide sequences for 370,000 different species, with yearly rates of increase in certain data types such as transcriptomics of nearly 50% (Benson *et al.*, 2017). Biological research had entered a new era, in which data processing and analysis require informatics tools, leading to the emergence of the field of bioinformatics.

Gene function analysis in the genomics era. The Gene Ontology project was started at the beginning of the genomics era, when the rapidly increasing number of sequenced genomes made it necessary to have a way to describe gene products' functions that would be applicable to all realms of life. Up until that point, in each species the vast majority of the genes had not been identified nor studied. The relatively few genes that had been identified had some amount of knowledge associated with it (even if very small): Either a mutant and its associated phenotype, an enzymatic activity, a genetic interaction, etc. The availability of entire genome sequences, and moreover, the sequences of genomes of multiple species, increased by many orders of magnitude the number of different genes for which we at least knew the existence. However, there was no systematic way to describe gene functions, with different biology communities having developed their own, often organism-specific nomenclatures. For example, the term 'budding' has different meaning when describing plant propagation, tooth formation initiation, or asexual reproduction that occurs for example in *Saccharomyces cerevisiae*. The Gene Ontology was created to meet that need. The specific question that got the project started was the need, formulated by Prof Michael Ashburner, to classify all genes from *Drosophila*, the model system he was studying and whose genome had just been sequenced, and have the same classification scheme for other model organisms so that gene functions (and hence, genomes), could be compared (Lewis, 2017). The ability to compare homologous and orthologous genes allows formulating research hypotheses for uncharacterized genes, or when certain biological modules are well conserved, providing a model of a gene's function.

Why an Ontology?

In information sciences, an ontology is a computational structure that describe entities and relationships of a domain of interest in a structured, and hence computable format. Ontologies are composed of a set of entities, also called classes, arranged into a hierarchy from the general to the specific (Hastings, 2017). This structure is powerful because it is amenable to computational analysis using logical reasoning. Moreover, linking ontology classes with biological entities provides a structured classification of gene function which itself can be further used for analysis of experimental data.

The Gene Ontology

Organisation of GO. The overarching goal of the GO project is to provide life science researchers with current functional information concerning gene functions and the cellular context under which these occur. GO is a structured, controlled vocabulary that formally represents biological knowledge. In the GO system, the terms are subdivided in three non-overlapping ontologies (also known as aspects): Molecular Function (MF), which describe the molecular activities of gene products; Biological Process (BP), the pathways and larger processes made up of the activities of multiple gene products, and Cellular Component (CC), that illustrate where gene products are active (Ashburner *et al.*, 2000). These aspects are non-redundant and share a common space of identifiers and a well-specified syntax.

Classes and definitions. In GO, each term defines a *class*. The class itself is defined in two different ways: Textually, with a human-readable definition, and logically by relationships to other terms in the ontology and which can be computed over. The most common relation is *is_a*, which represents the ontological definition of a class (*i.e.*, it describes what the term *is* relative to others named classes in the ontology). Other commonly used relations in GO include *part_of*, representing partonomy between classes. For example, the brain is *part_of* the body.

Molecular functions are generally described as *types* of other functions, using the *is_a* relationship. For example, *DNA helicase activity* and *lyase activity* are both types of catalytic activity, and hence are related to *catalytic activity* by *is_a* relationships.

Biological process has three main types of relations, *is_a*, *part_of*, and *regulates*. The *is_a* relation represents types of a process, for example *mitotic DNA replication* (GO:1902969) is a particular type of *nuclear DNA replication* (GO:0033260). On the other hand, sub-processes are represented by *part_of* relations: *mitotic DNA replication* is a step of the *cell cycle* (GO:0000278). Biological regulation is a type of Biological Process, represented by the relation *regulates* and two more specific relations, *negatively regulates* and *positively regulates*.

Each class must be defined as a *is_a* class of another class, to ensure that the ontology is completely representing all classes logically. In addition, each class may have multiple relationships to other classes' terms. This allows for more expressivity than a simple hierarchy. This structure makes GO a directed graph with terms as nodes and relationships as edges. Fig. 1 graphically illustrates the structure of GO.

An increasingly larger number of terms are being defined with equivalence axioms or logical definitions (Gene Ontology Consortium, 2015). These use explicitly defined relations from the Relations Ontology to produce a description for terms that is amenable to logical reasoning. An example is shown in Fig. 2. The equivalence axiom makes the class unique relative to all other classes in the ontology.

As of November 2017, the full ontology contained 49,968 terms: 4146 cellular components, 29,669 biological processes and 11,140 molecular functions. The ontology also contains 73,776 explicitly encoded *is_a* relationships, 30,879 explicitly encoded *part_of* relationships, and 20,564 explicitly encoded *regulates*, *negatively regulates* or *positively regulates* relationships.

GO uses external ontologies extensively to represent other types of terms such as chemicals (ChEBI ontology (de Matos et al., 2010)), vertebrate anatomical parts (Uberon (Mungall et al., 2012)), plant parts (Cooper et al., 2013), cell types (Bard et al., 2005), and sequence features (Eilbeck et al., 2005).

Managing changes in the ontology. GO undergoes frequent revisions: changes of relations between terms, addition of new terms, or term removal. Terms are never deleted from the ontology, but their status changes to "obsolete" and all relationships to other terms are removed (Rhee et al., 2008). Term obsolescence may lead to loss of annotations if the responsible group does not re-house the annotations under a more appropriate term. Other types of changes such as changes to the relationships between terms and term merges do not impact annotations, because annotations always refer to specific terms, not their position within the GO. However, these changes can affect the analyses done using the ontology.

Fig. 1 Illustration of the Gene Ontology structure. Paths of the term *regulation of cell projection assembly*, GO:0060491 to its root term. GO is a directed graph with terms as nodes and relationships as edges; these relationships are either *is_a*, *part_of*, *has_part*, or *regulates*. In its basic representation, there should be no cycles in this graph, and we can therefore establish parent (more general) and child (more specific) terms. Reproduced from PMID:27812933.

```

name: L-glutamate import across plasma membrane
equivalentTo:
  transport that ('has target start location' some 'extracellular region')
  and ('has target end location' some cytosol)
  and (imports some 'L-glutamate')
  and ('results in transport across' some 'plasma membrane')
inferred classifications:
  'import across plasma membrane'
  'L-alpha-amino acid transmembrane transport'
  'L-glutamate import into cell'

```

Fig. 2 Logical definition for the class L-glutamate import across plasma membrane.

GO Annotations

Annotation objects. Ideally, gene ontology terms are associated to the biological entity having the function being captured, i.e. the gene product. In practice, database entries for *genes* are often used as a proxy for gene products. Gene products can be either a protein, a non-protein-coding RNA, or any other gene product, including isoforms and post-translationally-modified proteins, which can be captured using the Protein Ontology (Natale *et al.*, 2017). Moreover, GO allows capturing isoform-specific data when appropriate. Identifiers are for example UniProtKB isoform identifiers, such as P12345-2.

Semantics of a GO annotation. The association of a GO term and a gene product means that the gene product inherently possesses an activity (or, more precisely ontologically, the potential for that activity) or a molecular role (MF term), directly participates in a process (BP), and that its function occurs in a specific cellular localization (CC) (Ashburner *et al.*, 2000). Therefore, transient localizations such as endoplasmic reticulum and Golgi apparatus for secreted proteins are not in the scope of GO. Dynamic localizations such as the movement to the mitotic spindle during cytokinesis should be captured, as these correspond to locations at which the gene product is active. A thorough overview of the meaning of biological function in GO has been written by Thomas (2017).

A gene product can be annotated using as many GO terms as necessary to completely describe its function, and the GO terms can be at varying levels in the hierarchy, depending on the state of knowledge when the annotation was made. If a gene product is annotated to any particular term, then the annotation also holds for all the is-a and part-of parent terms. Annotations to more granular terms carry more information.

Certain annotations additionally contain *qualifiers*: *contributes_to*, *colocalizes_with* and *NOT*. The qualifier can profoundly change the meaning of an annotation, in particular the *NOT* qualifier, which means that a gene protein does not have a particular function, or does not participate in a given process, or is not localized to the a given cellular component. *Contributes_to* is used for molecular function annotations, and means that while the gene product has some role in the molecular function, on its own it does not possess the function. This usually applies to a protein complex: for example, each RNA polymerase subunit contributes to RNA polymerase activity, but none of the individual subunits has that function on its own. *Colocalizes_with* is used to capture a localization near an organelle, but when the gene product is not an intrinsic part of the organelle. Details about the qualifiers used in GO and their definitions can be found on the GO website, (see “Relevant Websites” section).

Data provenance. The supporting evidence for each annotation is captured using evidence codes and references. Evidence Codes represent the type of information from which the annotation is derived, and are grouped in five broad categories: experimental evidence codes, computational analysis evidence codes, author statement evidence codes, curatorial statement evidence codes, and automatically assigned evidence codes (Fig. 3). Experimental evidence codes represent data captured from experimental data. The data can be derived from a direct assay (*IDA*), from a mutant (*IMP* and *IGI*), from a physical interaction (*IPI*), or from the expression pattern of a gene product (*IEP*). The GOC has recently introduced new evidence codes to label data derived from high throughput experiments: *High throughput direct assay evidence* (*HDA*), *high throughput mutant phenotype evidence* (*HMP*), *high throughput genetic interaction evidence* (*HGI*), and *high throughput expression pattern evidence* (*HEP*). The largest fraction of annotations is attributed automatically, e.g., annotations via the InterPro resource (Burge *et al.*, 2012).

Manual annotation of Panther protein families (Mi *et al.*, 2017) based on the phylogenetic relationships between the members of these protein families (PMID:21873635) are assigned the evidence code *Inferred from Biological Aspect of Ancestor* (*IBA*). Curators also manually assign annotations derived from the known functions of similar sequences (*ISS* and related methods *ISA*, *ISM* and *ISO*). Curators can also capture annotations based on statements that can be traced to an original publication (*TAS*) and they can make statements based on well-known biological knowledge using the *Inferred from Curator* (*IC*) code (for example, a protein

Experimental annotations	Automatically assigned annotations
IDA: Inferred from Direct Assay	IEA: Inferred from Electronic Annotation
IPI: Inferred from Physical Interaction	
IMP: Inferred from Mutant Phenotype	
IGI: Inferred from Genetic Interaction	
IEP: Inferred from Expression Pattern	
High throughput experimental annotations	Curated non-experimental annotations
HTP: High ThroughPut evidence	IBA: Inferred from Biological Aspect of Ancestor
HDA: High throughput Direct assay evidence	ISS: Inferred from Sequence or Structural similarity
HMP: High throughput Mutant Phenotype evidence	- ISO: Inferred from Sequence Orthology
HGI: High throughput Genetic Interaction evidence	- ISA: Inferred from Sequence Alignment
HEP: High throughput Expression Pattern evidence	- ISM: Inferred from Sequence Model
	TAS: Traceable Author statement
	IC: Inferred by Curator
	ND: No biological Data available

Fig. 3 The main evidence codes used by the GOC project.

with transcription factor activity is expected to be active in the nucleus of eukaryotic cells). Finally, when no data are available for an aspect of GO for a given protein, a curator can annotate the root term of the ontology (*molecular_function*, *biological_process*, or *cellular_component*), and use the evidence code *ND*. More details about the use of evidence codes and how they are used in GO can be found in [Gaudet et al. \(2017\)](#); [Chibucos et al. \(2017\)](#).

The Reference represents the source of the annotation. For annotations based on experimental evidence, the Reference contains the PubMed (PMID or PMC) accession ID. When the evidence code denotes an automatically assigned annotation, the reference will contain one of the GO_REF codes maintained by the GO Consortium (see “Relevant Websites” section) that details the automated assignment methods.

Contributing groups. Various contribute annotations, including UniProt ([UniProt Consortium, 2014](#)), Mouse Genome Informatics ([Drabkin et al., 2012](#)), Saccharomyces Genome Database ([Hong et al., 2008](#)), Wormbase ([Harris et al., 2010](#)), Flybase ([dos Santos et al., 2015](#)), dictyBase ([Gaudet et al., 2011](#)), EcoCyc ([Keseler et al., 2009](#)) and the Functional Gene Annotation group at University College London ([Buchan et al., 2010](#)). While most funding for these efforts come from the US National Institutes of Health, many smaller funding streams have enabled a wide consortium of groups to contribute to GO resources.

In addition to the above-mentioned groups who have dedicated resources to produce GO annotations, the GOC is fortunate to have fostered collaborations with research groups that can improve the ontology, the annotations, or both. Major revisions or expansions of a specific GO domain are often undertaken in consultation with domain experts. Notable successful collaborative projects include that of the immune system ([Diehl et al., 2007](#)), heart development ([Khodiyar et al., 2011](#)), kidney development ([Alam-Faruque et al., 2014](#)), fetal development ([Wick et al., 2014](#)), muscle processes and cellular components ([Feltrin et al., 2009](#)), transcription ([Tripathi et al., 2013](#)), and cilium biology ([van Dam et al., 2013](#)). Some model organism databases invite direct contributions from researchers, such as PomBase for *Schizosaccharomyces pombe*, who has developed curation tool, CANTO ([Rutherford et al., 2014](#)).

Members of the broader community are welcome to suggest improvements to the ontology and annotations. The GO project is now managed via GitHub (see “Relevant Websites” section). Users are welcome to submit their feedback via the tracker. Details about contributing to GO are available on the GOC website (see “Relevant Websites” section).

Main Applications of the Gene Ontology

One of the main uses of GO is to analyze the results of high-throughput experiments. Two types of analyses can be done to interpret this type of data. One is to group the location or function of genes that are over- or under-expressed (enrichment

analysis). In functional profiling, GO is used to determine which processes are different between sets of genes. This is done by using a likelihood-ratio test to determine if GO terms are represented differently between the gene sets (Mi *et al.*, 2013).

GO can also be used to infer the function of unannotated genes. Gene prediction with significant similarity to annotated genes can be assigned one or several of the functions of the characterized genes (Conesa and Götz, 2008; Meehan *et al.*, 2013). Other methods such as the presence of specific protein domains can also be used to assign GO terms (Burge *et al.*, 2012; Pedruzzi *et al.*, 2015).

Another usage of GO is as a dictionary to support text mining of the biomedical literature. In this case domain-specific concepts derived from GO are used to classify the literature or attach concepts to documents (Ruch, 2017).

Accessing Gene Ontology Project Data

Ontology: There are three different editions of the GO, in increasing order of complexity: *Go-basic*, *go*, and *go-plus*.

Go-basic: The basic edition of the GO, filtered such that annotations can be propagated up the graph (*i.e.*, it does not contain any cycles). The relations included are *is a*, *part_of*, *regulates*, *negatively_regulates*, and *positively_regulates*. Moreover, *go-basic* excludes relationships that cross different aspect of the ontology. This version is available in Open Biological Ontology (OBO) format only.

Go: This core edition of the GO includes additional relationship types, including some that span the three GO aspects, such as *has_part* and *occurs_in*, connecting the otherwise disjoint hierarchies found in *go-basic*. This version of the GO ontology is available in OBO format and in OWL-RDF/XML.

Go-plus: This is the most expressive edition of the GO; it includes more relationships than the *go* file, as well as connections to external ontologies, including the Chemical Entities of Biological Interest ontology (ChEBI; (Hastings *et al.*, 2013)), the Uberon anatomy ontology (Mungall *et al.*, 2012), and the Plant Ontology for plant structure/stage (PO (Cooper and Jaiswal, 2016)). It also includes import modules that are minimal subsets of those ontologies. This version of the GO ontology is available in OWL-RDF/XML.

See “Relevant Websites” section for instructions to download those files.

Ontology subsets. Gene Ontology subsets (also known as *slims*) are reduced versions of the ontology containing fewer terms and usually designed to summarize and aggregate the available data for specific application; for *e.g.*, species-specific subsets or more generic subsets with informative terms in various categories). Subsets are particularly useful for giving a high level summary of GO annotations. Further information is available from the GO website (see “Relevant Websites” section).

Annotations. Annotations are available in Gene Association File format (GAF) (see Relevant Websites Section). A newer format, GPAD, is designed to be more normalized than GAF, and is intended to work in conjunction with a separate format for exchanging gene product information (GPI). Details about the contents of the GAF format can be found in Gaudet *et al.* (2017).

Web interfaces. Association of GO terms with gene products is made by different groups who contribute the data to a central database. That data is disseminated by the GO consortium via the AmiGO platform (see “Relevant Websites” section), the official web-based open-source tool for querying, browsing, and visualizing the Gene Ontology and annotations. AmiGO supports basic searching, browsing, the ability to download custom data sets, and a common question wizard interface.

Best practices for using GO data. GO and its annotations are updated and released daily. Therefore, for reproducibility and correct reporting of methodology, researchers should provide the data at which files used for a particular analysis were downloaded (Blake, 2013).

Future Directions

The expressivity of GO annotations is limited by the fact that the current paradigm associates a gene product with a GO class, but there are no links between independent annotations. One example is a steroid hormone receptor, which act as a hormone receptor when localized in the cytosol, and upon binding to its ligand, translocates to the nucleus where it acts as a transcription factor. In GO, the gene encoding that receptor would be annotated to both molecular functions (transcription factor activity and receptor activity) and two cellular components (cytosol and nucleus), but the connections between these annotations are unfortunately not part of the data model. The GO Consortium is working towards the elaboration of a new data model, the GO-Causal Activity Model (GO-CAM), which links different annotations to each other as appropriate, to produce a more complete model of biology. Improving the expressivity of GO annotations will enable researchers working on logic-based models in systems biology to use the rich GO data to enhance their models.

Closing Remarks

GO is among the most significant informatics resources in the biomedical research community, providing scientists a way to interpret genomic, proteomic and transcriptomic data, and discover gene function and build genomic profiles. Understanding the design and data production in GO is essential for researchers to make the best use of this extensive resource.

Biographical Sketch

Pascale Gaudet works in the field of biocuration since 2003, working on various projects, including the Model Organism Database dictyBase, the neXtProt database on human proteins of the Swiss Institute of Bioinformatics (SIB), and the Gene Ontology project. Since 2017 Pascale Gaudet is the Project Manager of the GO project. Additionally, Pascale Gaudet is one of the founding members and the first chairperson of the International Society for Biocuration (ISB). The ISB seeks to connect biocurators, developers, and researchers with an interest in biocuration, both amongst themselves and with the users and funders of biological informatics resources.

Protein Functional Annotation

Pier Luigi Martelli, Giuseppe Profiti, and Rita Casadio, University of Bologna, Bologna, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Functional annotation is one of the most crucial activities of a Bioinformatician. As a matter of fact, as long as a sequence of characters, no matter of nucleic acids or protein residues, is a string, biologists can make little usage of it. It is therefore mandatory to try to endow with structural and functional features any string of biological origin. In the following, in spite of being deeply aware of the relevance of the annotation of the whole genome in different species, we will focus into the problem of protein sequence annotation that starts immediately after the recognition of a coding region in the DNA sequence. Functional annotation is a prerequisite for the inclusion of the sequence in the public archive/database.

UniProt

Today, the largest public repository of protein sequences is the Universal Protein Resource (UniProt) (<http://www.uniprot.org/help/about>). UniProtKB (Uniprot Knowledgebase, UniProtKB/Swiss-Prot 2017_02) comprises two databases, TrEMBL and SwissProt. The difference consists in the quality of the annotation. In SwissProt (including 553,655 sequences), protein annotation is manually curated with the aid of literature and computational analysis; in TrEMBL (including 77,483,538 sequences) annotation is automatically computed and not reviewed. More than 95% of the protein sequences come from the translations of coding sequences (CDS) submitted to the EMBL-Bank/GenBank/DBJ nucleotide sequence resources of the International Nucleotide Sequence Database Collaboration (INSDC). The problem of protein annotation starts here and it is extremely relevant, since all our molecular knowledge is based on what the database contains.

How many proteins do we know? For each record, Uniprot includes indications relative to the protein existence. The protein existence can derive from wet experiments (e.g., 3D structure, biochemical characterization, protein–protein interaction). In this case, the record lists “Evidence at protein level.” Alternatively, the protein existence may be associated with the existence of a transcript (“Evidence at transcript level”). It is quite evident from [Table 1](#) that proteins with experimental evidence and evidence at the transcript level are only 1.5% of the total database. About 23% of the proteins are inferred by sequence similarity with existing orthologues in evolutionarily related species. The remaining 75% are “predicted proteins,” without any evidence of the above qualifiers (http://www.uniprot.org/docs/pe_criteria). The percentage of predicted proteins is much less in the SwissProt database (2.5%). Interestingly, SwissProt contains some 0.3% of “Uncertain” proteins, so to say proteins that may be products of pseudogenes, dubious Coding DNA Sequences and genes, but that have been manually curated. Protein allocation in TrEMBL or SwissProt is indeed entirely dependent on the manual curation or automatic procedure of the annotation (<http://www.uniprot.org/help/about>). From the statistics, one may conclude that we know with some experimental evidence only 1.7% of the proteins listed in Uniprot KB (78,037,193).

The Gene Ontology

The Gene Ontology project started in 1998 with the goal of providing a controlled vocabulary of terms for describing gene product functional characteristics in a computationally feasible way, by associating words, actions and sentences suited to characterize the complete function of a gene with numbered terms (GO terms). GO terms have three major routes: biological process (BP), molecular function (MF) and cellular components (CC). Each route is hierarchically organized from more general (less informative) to more specific terms (leaves). Since its foundations, the Gene Ontology database has developed formal ontologies and constantly has been revised to include new discoveries. Information was derived from experiments described in some 100,000 peer-reviewed scientific papers (<http://www.geneontology.org/>). AmiGO 2 (<http://amigo.geneontology.org/amigo>) is a tool that allows the gene-GO term association search in the database. The release (March 2017) of GO includes 29,385 BP, 10,543 MF and

Table 1 Some statistics of the latest release of UniProtKB (release 2017_02).

<i>Protein existence</i>	<i>#UNIPROT/TrEMBL entries</i>	<i>#UNIPROT/SwissProt entries</i>
Evidence at protein level	125,718	94,730
Evidence at transcript level	1,066,148	57,857
Inferred from homology	17,797,259	385,421
Predicted	58,494,413	13,697

4045 CC terms. A GO term has experimental origins when the gene/gene product has a physical characterization in a paper that describes the corresponding association. Experimental Evidence codes, as well as Computational Analysis and Author Statement evidence codes are listed at <http://www.geneontology.org/page/guide-go-evidence-codes>

Foundations of Functional Annotations

Our information on the biological complexity can be dissected into three major levels of knowledge: sequence, structure, and function. Accordingly, we may think of the relationships among different spaces (universes). **Fig. 1** shows the relationships among the sequence and the structure space. Information is maximal when we know the structure of the protein, stored in the Protein Data Bank (PDB, <http://www.rcsb.org/pdb/home/home.do>). The structure of the protein is mainly derived from its electron density determination, and this allows us to determine even its function based on quantum molecular computations. Problem is that we know the structure of some 124,114 proteins (PDB, March 2017); however, only 40,463 UniProt entries are linked to nearly all the PDB entries. This is mostly due to redundancy of structures with respect to the same reference sequence. In conclusions, we have information based on the structure for only 0.05% of the total number of sequences. These proteins are associated with about 23,000 experimental GO terms (**Table 2**). Ideally, we can then connect the space of functions with that of structures and sequences. The question poses as to whether it is possible to infer functions from sequences, taking advantage of what it can be derived in terms of basic association rules from known structures and their associated sequences and functions. Evolutionary relationships can help: we know from biological observations that functions are conserved through species, that orthologous proteins conserve functions, have similar structures and similar sequences. We also know that even when alignment methods fail in retrieving significant scoring below 30% sequence identity, proteins may conserve structures and functions, being included in what we call remote homologs. All this biological information, related to the general concept of evolution, has been promoting in the last decades an enormous effort in developing computational methods. Although different and based on different strategy, different methods try to address the problem of how is it possible to fill the gap between the deluge of protein sequences and their structural and functional annotation.

The Annotation Process in UniProt

UniProt performs both expertly curated manual and automatic annotation (a flow diagram is reported at <http://www.uniprot.org/help/biocuration>) and highlights also the interplay between manual and automatic annotation.

Manual Annotation

Manual annotation in UniProt is a multistep-curated process that includes similarity search, feature prediction, and validation (http://www.uniprot.org/help/manual_curation). Details are described in the standard operating procedure (SOP) for UniProt manual curation (<http://www.uniprot.org/help/biocuration>).

Briefly, a sequence is aligned with other well-known sequences with alignment tools such as Blast, and information for its annotation derives from a variety of resources, including scientific literature, sequence analysis tools, phylogenetic and comparative genomics databases (Ensembl Compara, <http://www.ensembl.org/info/genome/compara/index.html>, and other species-specific collections). A protein is practically annotated with InterPro (<https://www.ebi.ac.uk/interpro/about.html>), a cluster of different resources that classifies sequences at superfamily, family and subfamily levels and comprises predictive models of protein functions from several databases. High-quality automated and manual annotation of proteins (HAMAP, <http://hamap.expasy.org/>) is part of the InterPro cluster for family classification. For association of functional GO terms to structural and functional features, InterPro integrates InterPro2GO that maps GO term to InterPro entries. The core of the classification scheme is the software package InterProScan that allows scanning sequences against InterPro features (<https://www.ebi.ac.uk/interpro/interproscan.html>) and integrating prediction of functional domains and important sites. For inclusion of distinguished features such as transmembrane regions and signal peptides, manual annotation follows a set of expert rules (<http://www.uniprot.org/help/transmem>; <http://www.uniprot.org/help/signal>).

Automatic Annotation

The automatic annotation process of UniProt is a multistep process performed by a pipeline that is based again on the protein classification schemes of InterPro. Once the structural and functional features are expertly determined, two prediction systems are active for the automatic annotation: UniRule and the Statistical Automatic Annotation System (SAAS). Both are essentially based on the application of rules (if conditions → then annotation), differently extracted. UniRule collects rules (some 5557 Identifiers (ID)) derived by curators from manually annotated entries and templates, and routinely annotates properties such as the protein name, functions (GO terms), catalytic activity, pathway membership, and subcellular location, along with sequence specific

information, such as the positions of posttranslational modifications and active sites. Similarly, SAAS generates automatic rules for functional annotation from expertly annotated entries in UniProtKB. The algorithm uses machine learning to find the most concise rule for an annotation based on the properties of sequence length, InterPro group membership and taxonomy. SAAS includes 13,674 IDs and can annotate protein properties such as function (GO term), catalytic activity, pathway membership, and sub-cellular location, with the exclusion of protein names and feature predictions. A sequence analysis method (SAM) is adopted to enrich records with extra sequence-specific information. Predictions of sequence features such as Signal, Transmembrane and Coil regions are computed by other prediction methods, including THMM, Phobius, and SignalP (<http://www.uniprot.org/help/sam>).

Our Present Knowledge

When addressing the problem of functional annotations, we should cope with what we know. In SwissProt, some 94,730 reviewed sequences with evidence at the protein level have links with some 93,843 PDB files and only 22,861 GO terms with experimental labels (Table 2). Some other 20,135 GO terms have only electronic indexes. The number of protein sequences with experimentally detected functions increases when we include proteins with evidence at the transcript level. Therefore, the actual situation is not particularly sound in terms of putative subsets to be adopted for training/testing specific computational methods to predict function from sequence. In the following, we will briefly review the actual state of the art methods (some of them have been already mentioned, being part of the InterPro consortium).

Computational methods have been implemented to associate uncharacterized proteins (targets) to terms describing the function, mostly complying with the Gene Ontology. In general, these methods compare a target to a set of annotated proteins in order to extract and transfer the functional terms. Different approaches are available, in relation to the information available for the target protein at the sequence and/or structure levels and to the similarity with the functionally characterized proteins (Chothia and Lesk, 1986). In the following methods are clustered according to their basic principles of implementation (Table 3).

Methods Based on Structure Similarity

When the target protein is endowed with experimental 3D structure, methods based on structure superimposition can be applied, relying on the observation that a high level of structural similarity among proteins generally implies functional similarity. This approach can be extended to proteins with modeled 3D structure, with limitations that strongly depend on the reliability of the model.

Methods for large-scale comparison of protein structures are therefore adopted to scan the target protein against the Protein Data Bank to retrieve annotation terms. Among them, CE (Shindyalov and Bourne, 2001), PDB-eFOLD (Krissinel and Henrick, 2004), DALI (Holm and Rosenström, 2010), VAST (Madej et al., 2014). They adopt different strategies to compare structures at the level of the backbone atoms. However, the conservation of the overall fold is not sufficient to ensure function similarity. A comprehensive structural classification of proteins domains is available at CATH (<http://www.cathdb.info/>, Sillitoe et al., 2015) and it clearly shows a high heterogeneity of functional terms for some of the folds, including TIM barrel fold, ferredoxin fold, and Rossmann fold.

The reliable association between structure and function requires the detailed conservation of the protein sites important for catalytic activity, substrate binding, and intermolecular interaction. Repertoires of 3D templates of enzyme catalytic sites are available at Catalytic Site Atlas (<http://www.ebi.ac.uk/thornton-srv/databases/CSA/>, Furnham *et al.*, 2014.) and Pocketome (<http://www.pocketome.org/>, Kufareva *et al.*, 2012).

When global structural alignments of the target do not retrieve significant results in the PDB, the recognition of structural motifs can assist the functional annotation. Methods implementing local structure alignment, such as ProFunc (Laskowski *et al.*, 2005) can identify local regions, functionally relevant and conserved across several globally divergent structures. Putative active site pockets on the protein surface can be determined with geometric-based approaches like Ligsite (Huang and Schroeder, 2006) and ProBIS (Konc *et al.*, 2015).

Methods Based on Sequence Similarity

When the 3D structure of the target proteins is not available, protein annotation is routinely performed by aligning the residue sequence against the annotated proteins available in sequence databases. The inference of functional similarity requires a higher sequence identity with respect to structural similarity. Generally, the more specific the function to be transferred, the higher the level of identity. Rost (2002) showed that less than 30% of the enzyme sequences sharing more than 50% identity have entirely identical EC numbers and enzymes with different specific functions can align with BLAST E-values below 10^{-50} . Moreover, multidomain proteins increase the complexity of the protein sequence–structure–function relationship and require a careful check of the extent of alignment length with respect to the target sequence (coverage).

BLAST (<https://blast.ncbi.nlm.nih.gov/Blast.cgi>) is nowadays considered as the baseline method for transferring function annotations upon similarity search against a database of annotated sequence. Due to the complex patterns of association between sequences and function, statistical procedures are routinely applied on the set of retrieved terms to strengthen the reliability of the transferred annotations. For example, the widely adopted Blast2GO (Götz *et al.*, 2008) weights each term by considering the number of retrieved sequences it is associated to and the evidence codes linked to the annotations in the database. Argot2 (Falda *et al.*, 2012) weights GO terms according to their semantic similarity relations and the alignment scores of the retrieved sequences.

Phylogenetic analysis has been also adopted to support the transfer of annotation (e.g., SIFTER, Sahraeian *et al.*, 2015), under the assumption that function evolves parsimoniously within a phylogeny, mainly by duplication events; the position of the query sequence in a phylogenetic tree is more informative than the mere sequence similarity. An alternative strategy to perform a reliable transfer of annotation is based on the preliminary similarity-based clustering of the protein universe into groups that can be functionally characterized on the basis of the existing annotations. COG (Galperin *et al.*, 2015) contains orthology-based clusters of microbial sequences and endows them with manually curated annotation. A complete nonhierarchical clustering of UniProt is at the basis of BAR3 (Profitti *et al.*, 2017): pairs of sequences sharing identity > 40% with an alignment coverage > 90% are linked to form a graph, whose connected components are extracted to form the clusters. Functional terms associated to clustered proteins are statistically tested for overrepresentation and significant annotation are assigned to the whole cluster. A new sequence falling in the cluster upon alignment inherits the validated terms.

Methods Based on Sequence Profiles and Motifs

Sequences sharing low level of identity with already characterized proteins present the hardest challenges to the process of annotation. Procedures based on sequence profiles are able to extend the range of application of annotation transfer. Sequence profiles are built starting from the multiple alignment of sequences or structures of protein domains already characterized at the functional level. Profiles are routinely represented with either position specific scoring matrices (PSSMs) or Hidden Markov Models (HMMs). Uncharacterized sequences can be aligned against a collection of profiles to retrieve remote similarities and transfer annotation. Profile representation allows increasing the sensitivity of searches by scoring in a different and family-dependent way substitutions and indels in each position of the alignment. The main difference among methods lies in the strategy adopted to build the collection.

Popular repositories of HMMs obtained after manual curation of multiple sequence alignments are PFAM (Finn *et al.*, 2016) and SMART (Letunic *et al.*, 2015), containing models for more than 16,000 and 1200 protein domains, respectively.

The NCBI Conserved Domain Database (CDD) collects PSSMs for curated domains, integrating information from 3D-structure, SMART, PFAM, COG and other external source databases (Marchler-Bauer *et al.*, 2017). On top of CDD, SPARCLE improves the annotation by analyzing the sequential order of the different domains associated to a protein (domain architecture) (Marchler-Bauer *et al.*, 2017).

CATH-Gene3D Functional Families (FunFams) is a compilation of 92,882 HMMs obtained starting from multiple structural alignments of domains belonging to the same CATH family and sharing the same function (Sillitoe *et al.*, 2013).

When also remote similarity search with sequence profiles fails, function annotation can exploit the presence of sequence motifs or fingerprints. They generally represent fragments of the sequence that, in the folded protein, are part of relevant active or functional sites, as highlighted in multiple sequence alignments. Motifs and fingerprints are usually represented with regular expressions or small sequence profiles. PROSITE (Sigrist *et al.*, 2013) and PRINTS (Attwood *et al.*, 2012) are two of the most popular resources, that are also included in the InterPro annotation pipeline.

Integrative and Machine Learning Based Methods

Function annotation of sequences sharing no detectable similarity with characterized proteins requires the development of integrative methods that try to bridge the gap by exploiting different sources of information, including the prediction of relevant features and the mining of interactomics and transcriptomics data. The information is integrated with different approaches, including the expert-driven definition of decision trees, the application of simple regression rules, and the implementation of machine-learning algorithms. The rules of associations between features and annotation are extracted with manual or automatic procedures by analyzing sets of characterized proteins available in datasets (training set). The unbiased estimation of the prediction performance on uncharacterized sequences requires to collect sets of annotated proteins (testing sets), separated and as different as possible from the training sets. This operation is sometimes difficult, in particular when different tools, trained on different training sets, are integrated. For that reason, critical assessment experiments are a useful way to estimate, compare and interpret the methods performance (see next session).

It is in the set of considered features that lies the major difference among the available tools.

FFPred (Minneci *et al.*, 2013) combines with support vector machines (SVM) information on residue composition and presence of low complexity regions and predictions of the following features: secondary structure, signal peptide, transmembrane regions, coiled-coil or disordered segments, phosphorylation and glycosylation sites.

The availability of experimental data on transcriptomics and interactomics leads to the so called “guilty by association” approach: coexpressed genes and proteins in physical or functional relation reliably share common functional features. For example, INGA (Piovesan *et al.*, 2015) combines information on sequence similarity, domain architecture and protein–protein interactions as derived from STRING. In MS-kNN (Lan *et al.*, 2013) a k-Nearest-Neighbor (kNN) system analyzes similar information, integrated with experimental data on gene expression. CombFunc (Wass *et al.*, 2012), combines with SVMs prediction of structural domains and ligand binding sites, sequence motifs, sequence similarity and conservation, protein–protein interaction data from STRING and MINT, coexpression data from CoexpressDB.

An alternative source of information to be integrated is the literature published in scientific papers: EVEX (Van Landeghem *et al.*, 2012.) analyzes the PubMed abstracts to mine information about relevant biomolecular events such as phosphorylation, regulation targets, binding partners, and several other, assigning confidence values to these events.

Critical Assessment of Function Annotation

As we mentioned in the previous section, the evaluation of the performance of methods for functional annotation requires the availability of testing dataset of annotated proteins not used, in any way, during the training phase of the method. Moreover, the comparison of different methods requires the adoption of uniform testing sets. In order to provide an independent and unbiased assessment of computational methods and to provide insights on the state-of-the-art of function annotation, in 2010 the first critical assessment of function annotation (CAFA, <http://biofunctionprediction.org/cafa/>), experiment was run, followed by two more editions in 2013 and 2016. CAFA was inspired by critical assessment of structure prediction (CASP) and critical assessment of prediction of interactions (CAPRI), devoted to the blind evaluation of computational methods for the prediction of the structure of proteins and of protein complexes, respectively. In CAFA experiments, organizers provide for the community a large set of sequences with unknown or incomplete function. The task consists in predicting Gene Ontology annotations for each of these sequences, before a fixed deadline. After the prediction deadline, the experiment enters the “annotation growth” period in which protein functions are expected to accumulate in public databases (6–12 months). The predictions of different methods are afterwards compared with the experimental annotation deposited in UniProt during the “annotation growth” phase.

The most updated assessment is the CAFA2, i.e., the 2013 edition (CAFA2, Jiang *et al.*, 2016). The benchmark dataset comprised 3681 sequences and 126 different prediction models were evaluated. Results show that the predictive performance is increasing with respect to the CAFA1 edition. Top-performing algorithms are specific for sub-ontology (molecular function, biological process, cellular component) and biological domain (prokaryota, eukaryota). The main index of evaluation is the F1-score, which is the harmonic mean of the precision ($\#$ of correctly predicted annotations / $\#$ of predicted annotations) and the recall ($\#$ of correctly predicted annotations / $\#$ annotations of the benchmark dataset). The best F1-scores reached on eukaryotic proteins are about 0.6, 0.4, and 0.5 for MF, BP, and CC, respectively. In the case of prokaryotes, F1-scores are higher for BP and CC (0.5 and 0.7, respectively). These results, although encouraging, show that there is plenty of room for improvement of the methods for automatic function annotation.

Acknowledgments

This work was partially supported by the Italian Ministry of Education, University and Research [PRIN 2010–2011 project 20108XYHJS] to P.L.M., [PON projects PON01_02249 and PAN Lab PONA3_00166] to R.C. and P.L.M; European Union RTD Framework Program [COST BMBS Action TD1101, Action BM1405] to R.C and University of Bologna [FARB 2012] to R.C. Protein Post-Translational Modification Prediction

Chi NI Pang and Marc R Wilkins, The University of New South Wales, Sydney, NSW, Australia

© 2019 Elsevier Inc. All rights reserved.

Introduction

Post-translational modifications (PTMs) of proteins involve the covalent modification of amino acid side chains or of the protein's N- and C-termini. There are two main types of PTMs. The first involve the enzymatic covalent addition of small molecules (e.g., phosphoryl group for phosphorylation) or polypeptide (e.g., ubiquitin for ubiquitination) to the amino acids, whereas the second involve the proteolytic cleavage of the polypeptide chain. The most common types of PTM additions include phosphorylation, acetylation, methylation, ubiquitination, and glycosylation (Fig. 1), of the more than 450 different types of PTM documented in the Uniprot Database (Bateman *et al.*, 2017).

There are many biological functions for post-translational modifications. One way in which the addition of PTM regulates the activity of a protein is through changing the conformation of the target protein, a function well-documented for phosphorylation (Lin *et al.*, 1996; Cohen, 2000). Other post-translation modifications act as a subcellular localization signal (e.g., phosphorylation, methylation, ubiquitination) (Hunter, 2007; Scott and Pawson, 2009), while fatty-acid modifications can be used to anchor a protein to membranes. Post-translational modifications can also affect the half-life of a protein. For example, ubiquitination of a protein can mark it for degradation via the ubiquitin-proteasome pathway (Ciechanover, 1994), while N-terminal modifications are well known to regulate protein stability (Varshavsky, 2011). The presence of PTMs can also affect protein folding and solubility (Tokmakov *et al.*, 2012).

In addition to the above functional roles, PTMs are known to modulate protein-protein interactions. Enzymes can act as 'writers' or 'erasers' of modifications (Beltrao *et al.*, 2013), often through transient binding with the target (Stein *et al.*, 2009). Protein interaction domains, a number of which are known, can mediate direct binding to the target proteins and act as a 'reader' for specific

Fig. 1 Chemical structures of several common types of modified amino acids. This figure shows the chemical structures of amino acids (black) and their chemical modifications (red). These include acetylated lysine and phosphorylated serine, threonine, and tyrosine, and different types of methylated residues, including mono-methyllysine (MML), di-methyllysine (DML), tri-methyllysine (TML), mono-methylarginine (MMA), symmetrical di-methylarginine (SDMA), and asymmetrical di-methylarginine (ADMA).

Fig. 2 Reversible tyrosine phosphorylation regulates the binding of SH2 domains to tyrosine phosphorylated peptides. A tyrosine kinase catalyzes the transfer of a phosphoryl moiety to a tyrosine residue, resulting in a phosphotyrosine residue. This reaction can be reversed by a tyrosine phosphatase. A phosphotyrosine residue in the peptide can be recognized and bound by SH2 domains (PDB: 1LKK; Tong *et al.*, 1996). The SH2 domain is shown binding to a tyrosine-phosphorylated peptide.

PTMs (reviewed in Seet *et al.*, 2006). For modifications which are reversible through the action of ‘writer’ and ‘eraser’ enzymes, the binding of the ‘reader’ to the modified protein can be dynamically regulated in response to signals upstream of the enzymes. An example of this is the binding of SH2 domains to phosphotyrosine residues, which can be reversed by a competing tyrosine phosphatase (Fig. 2; Seet *et al.*, 2006). In other cases, PTMs can modulate protein-protein interactions by changing the physiochemical properties (e.g., hydrophobicity and charge) of a binding interface (Winter *et al.*, 2014) and/or causing conformational changes that exposes the interaction surface (Venne *et al.*, 2014). Recently, systematic analysis of protein interaction networks has identified that proteins with a high number of interaction partners, also called network ‘hubs’, are often enriched for PTMs. This observation is further evidence that PTMs have important roles in regulating protein-protein interactions (Duan and Walther, 2015).

The ‘histone code’ is a well-known process in which PTMs regulate the recruitment of transcription factors and their regulatory factors to active chromatin regions (Bannister and Kouzarides, 2011). The histone code involves multiple types of PTMs that are located at different sites along the tail of histone proteins (Bannister and Kouzarides, 2011). Different combinations of PTMs, involving ‘PTM crosstalk’, lead to the binding of different transcription factors to the histones. Recently, it has been suggested that histones may not be unique in having a ‘modification code’ and other proteins, including p53 (Gu and Zhu, 2012), RNA polymerase II (Eick and Geyer, 2013) and FoxO (Calnan and Brunet, 2008) were reported to have diverse PTMs which regulate their binding with interaction partners. This led to the general hypothesis that ‘interaction codes’ may be widespread in the proteome (Winter *et al.*, 2014). Interestingly, modification enzymes may also be subjected to regulation by PTMs, which adds further complexity to the analysis of the PTM code (Venne *et al.*, 2014). Deciphering this code would require the analysis of multiple types of PTMs, knowing the specificity of modifying enzymes, and knowing the role of PTMs in modulating protein folding, stability, localization and protein-protein interactions (Prabakaran *et al.*, 2012; Venne *et al.*, 2014).

Large-scale PTM datasets (Dinkel *et al.*, 2011; Zanzoni *et al.*, 2011; Huang *et al.*, 2016; Bateman *et al.*, 2017) have been generated mainly from proteomic studies (Hornbeck *et al.*, 2015; Mínguez *et al.*, 2015). Such datasets have accelerated the development of PTM prediction tools. As for all software, vital steps for the development of these tools include defining the needs of the users, incorporating features that will address the needs, and ensuring that the tool is robust and achieves the desired goals. Recently, a comprehensive review of PTM prediction tools for 10 types of PTMs has been published elsewhere (Audagnotto and Dal Peraro, 2017). Accordingly, this article will not explore what all the existing PTM prediction tools are, but will explore the aims and hypothesis that are widely applicable to PTM predictions tools and will highlight a series of challenges involved in designing, engineering, and testing these prediction tools to achieve these aims.

What are the Criteria for Evaluating and Selecting a PTM Prediction Tool?

When evaluating PTM prediction tools, it is important to consider the number of steps that is involved in building and benchmarking the performance of the tool (Fig. 3), any of which could affect whether the tool is suitable for the need of the research project. The main steps involve the training dataset, the predictive of selection of features, the testing dataset, the machine learning algorithm, the evaluation dataset, the benchmarking approach and the performance metrics. Below, we illustrate the critical factors that influence the performance of PTM prediction tools through a number of case studies.

Case Studies on PTM Prediction Tools

Prediction of Phosphorylation Sites

PhosphoPredict

PhosphoPredict is a human kinase-specific phosphorylation site prediction tool developed by Song *et al.* (2017) (Table 1). This tool is of particular interest as it uses a combination of feature selection and protein-protein interaction to predict phosphorylation sites. The tool predicts phosphorylation sites for 12 human kinase families, including ATM, CDKs, GSK-3, MAPKs, PKA, PKB, PKC, and SRC. The

Fig. 3 Flow chart illustrating the process for developing a PTM prediction tool. Known PTM sites and sites known not be modified by the same type of PTM are collected. Datasets can be split into three, to generate a training dataset, the testing dataset, and an independent evaluation dataset. The features (also called predictors) of the model are defined (e.g., predicted surface accessibility and predicted intrinsically disordered regions). These features can be used directly for machine learning. Optionally, a subset of features which are least redundant and best describe the training dataset can be chosen using a feature selection algorithm. The training dataset, the testing dataset and the selected features can be used to train the machine learning algorithm and to develop the PTM prediction tool. The performance of the machine learning algorithm is benchmarked using the independent evaluation dataset and the results are then reported using various performance metrics (e.g., sensitivity, specificity, and accuracy).

Table 1 Case studies on post-translational modifications prediction tools

Name of tool and reference	Species specific?	Enzyme specific?	Dataset	Features ^a	Machine learning algorithm
Phosphorylation					
PhosphoPredict (Song <i>et al.</i> , 2017)	Human only	Yes, 12 kinase families	Phospho.ELM	Amino Acid Type, PSS, PSA, PIDR, Gene Ontology, Protein Domains, KEGG Pathways, Protein-Protein Interactions from STRING. Maximum Relevance Minimum Redundancy features selection	Random forest
ELM (Dinkel <i>et al.</i> , 2016)	Many organisms	Yes	Eukaryotic Linear Motif database and Phospho.ELM	Regular Expression Patterns, PSS, PSA, PIDR, and Protein Domains	Regular expression matching
Acetylation					
GPS-PAIL (Deng <i>et al.</i> , 2016)	Seven eukaryotes including Human and Yeast	Yes, seven histone acetyl-transferase (HAT)	702 non-redundant HAT-specific acetyllysine sites for 205 proteins	Sequence + / - 30 amino acids surrounding acetylation sites included	Simulated annealing to train scoring matrix and position specific weights. Optimization of motif length.
Methylation					
GPS-MSP (Deng <i>et al.</i> , 2017)	Many organisms	No, but specific to type of methylation	1521 meth-K from 962 proteins, and 3900 meth-R sites from 1751 protein	Sequence + / - 30 amino acids surrounding methylation sites included	Simulated annealing to train scoring matrix and position specific weights. Optimization of motif length.
Ubiquitination					
Nguyen <i>et al.</i> (2016)	Many organisms	No, but use clustering to predict putative motifs	2566 ubiquitination sites	Amino acid composition, amino acid pairwise composition, and PSSM	Support Vector Machine, Maximal Dependence Decomposition

^aPSS: Predicted Secondary Structure; PSA: Predicted Solvent Accessibility; PIDR: Predicted Intrinsically-Disordered Region; PSSM: Position-specific scoring matrix.

human phosphorylation sites and their kinase-specificity were obtained from Phospho.ELM (Dinkel *et al.*, 2011). A wide-range of predictive features are utilized, which includes those that are sequence-based, including amino acid type, predicted secondary structure (Wagner *et al.*, 2005), predicted solvent accessibility (Wagner *et al.*, 2005) and predicted intrinsic-disorder (Ward *et al.*, 2004). In addition, functional features were also used for predictions, including GO annotations (Carbon *et al.*, 2017) and protein domains of the query substrate protein (Finn *et al.*, 2016, 2017), KEGG biochemical pathways (Kanehisa *et al.*, 2016) and protein-protein Interactions (Szkarczyk *et al.*, 2017). These functional features are represented as categorical labels with one feature for each category.

Song *et al.* (2017) used the feature selection tool called maximum Relevance Minimum Redundancy (mRMR) (Peng *et al.*, 2005) to identify the most important subset of features for each kinase, which led to increased prediction performance. These features were used in the Random Forest (Breiman, 2001; Liaw and Wiener, 2002) machine learning algorithm, trained using five-fold cross-validation. Independent datasets from PhosphoSitePlus (Hornbeck *et al.*, 2015) and Uniprot (Bateman *et al.*, 2017) were used to verify that the tools were not affected by overfitting. The benchmarking resulted in high specificity (88.3%–96.7%) but variable sensitivity (29.2%–80.5%) for different kinases. PhosphoPredict was found to have better or similar performance as compared to other tools, including KinasePhos (Huang *et al.*, 2005), PPSP (Xue *et al.*, 2006), GPS (Xue *et al.*, 2006), and Musite (Xue *et al.*, 2006). Together, this tool highlights how a careful and well-informed design, that considers many aspects of PTMs, can lead to high quality predictions.

Eukaryotic linear motif (ELM)

The ELM database contains kinase-specific phosphorylation motifs represented as regular expression patterns, which enable users to predict the presence of kinase-specific phosphorylation sites within query protein sequences (Table 1) (Gouw *et al.*, 2017). The ELM database currently has 20 kinase-specific phosphorylation motifs and 12 kinase binding motifs and has recently been updated to include new motifs for CDKs, MAPKs and Plks (Gouw *et al.*, 2017). For a user-defined sequence, the tool can identify matches to entries in the Phospho.ELM database (Dinkel *et al.*, 2011), including experimentally identified phosphorylation sites and their kinase specificity if known. Users can also search the companion Switches.ELM database, which contain a list of sites in which the presence or absence of phosphorylation is known to affect protein-protein interaction (Van Roey *et al.*, 2013). In addition to kinase-specific phosphorylation sites, other types of modifications with known conserved motifs in ELM includes N-glycosylation, N-myristoylation, O-fucose modification, O-glucose modification, S-palmitoylation, sumoylation, and enzyme-specific peptide cleavage sites. The ELM database also contains annotations for conserved motif regions, also called Short Linear Motifs (SLiMs). SLiMs are compact linear sequences on average six amino acids in length, preferentially found in intrinsically disordered regions and involved in PTMs, molecular targeting or protein-protein interaction interfaces (Davey *et al.*, 2012).

In ELM, users can apply filters to increase the specificity of their motif searches. These include filters for motifs present in specific taxonomic groups or cell compartments. The probability filter is based on a score calculated from multiplying the probabilities of occurrence of each amino acid within the regular expression pattern. This filter can be used to reduce matches to degenerate motifs. The globular domain filters identify structurally ordered domains, which include predicted protein domains from Pfam (Finn *et al.*, 2016) and SMART (Letunic and Bork, 2017) and predicted globular regions from GlobPlot (Letunic and Bork, 2017). Via *et al.* (2009) showed the utility of structural filters for phosphorylation, which can be used to prioritize matches to disordered regions. Predicted secondary structures from SMART are used as a proxy for surface accessible loops. The disordered region filters include GlobPlot and IUPred (Linding *et al.*, 2003). Unlike many other PTM prediction tools, which rely on machine learning algorithms whose predictive mechanisms are opaque, the ELM database provides clear information on why a site was predicted. The predictions made by ELM are based on known kinase-specific phosphorylation motifs and sequence and structural features. These can be visualized as sequence tracks, which enables users to inspect the structural environment, motifs or other PTMs surrounding the phosphorylation site, thus providing a rich functional and structural context.

Prediction of Acetylation Sites

GPS-PAIL

The GPS-PAIL tool (Deng *et al.*, 2016) predicts acetylation sites that are specific to seven histone acetyltransferases (HATs): CREBBP, EP300, HAT1, KAT2A, KAT2B, KAT5 and KAT8 (Table 1). Few tools can predict acetylation sites specific to single acetyltransferases (Li *et al.*, 2012; Wang *et al.*, 2012; Deng *et al.*, 2016) and thus GPS-PAIL is of particular interest. Since not all acetyltransferases are present ubiquitously, Deng *et al.* (2016) also checked for the presence of each acetyltransferase in the proteomes of seven eukaryotic species. The training dataset included 702 experimentally determined acetyltransferase-specific acetylation sites for 205 proteins from seven eukaryotes, with 544 sites for 160 human proteins. The method uses the BLOSUM62 amino acid substitution matrix to compare a query site with known enzyme-specific acetylation sites; predicted acetylation sites have a high score. Simulated annealing was used to train position-specific weights and to mutate the BLOSUM62 matrix to achieve better predictions. This is a complementary method to other commonly used machine learning tools, requiring a problem and domain-specific ‘coding scheme’ to describe the search space (Gouw *et al.*, 2017); in this case it was the BLOSUM62 matrix and the position specific weights. The use of simulated annealing is notable as it is an active research area. Optimal motif length in GPS-PAIL was identified through an exhaustive search. Analysis of the sequence motifs surrounding acetylation sites of each acetyltransferase highlighted their sequence specificity, with K, R, G and A residues most often enriched in these motifs.

Performance evaluation of GPS-PAIL was carried out through leave-one-out cross-validation and N-fold cross-validation (Deng *et al.*, 2016). Among the seven acetyltransferases, the tool achieved a high specificity of 80%–95% but considerably lower

sensitivity of 38%–57.5%. Of the 10,505 experimentally determined acetylation sites from 4488 human proteins, the tool predicted the acetyltransferase responsible for 1492 sites (14.2%) and 913 proteins (20.34%), consistent with low sensitivity. GPS-PAIL was found to be more efficient for predicting acetyltransferase-specific sites for mammalian and plants as compared to other proteomes. The majority of acetylation sites were found to be targeted by one acetyltransferase only, while no acetylation sites were the target of all seven acetyltransferases, which suggests acetylation sites tend to be acetyltransferase-specific.

Prediction of Methylation Sites

GPS-MSP

Methyltransferase-specific protein methylation motifs have been described (e.g., [Hamey et al., 2016](#)) however, to the best of our knowledge, there is currently a lack of prediction tools for methyltransferase-specific protein methylation sites. Thus the tools predict sites, in a general sense, but not the possible methyltransferases that may be responsible. [Deng et al. \(2017\)](#) developed a suite of prediction tools (GPS-MSP) specific for different types of protein methylation, including mono-, di-, and tri-methyllysine, and mono-, symmetric di-, and asymmetric di-methylarginine. Separate prediction models for each type of methylation were shown to improve prediction accuracy. The same algorithm as GPS-PAIL (above) was used for GPS-MSP. The training dataset contained 1521 methyllysines from 962 proteins, and 3900 methylarginine sites from 1751 proteins. For different types of methylation sites, leave-one-out cross-validation and receiver operating characteristic analyses showed that the sensitivity ranged from ~35% to 50% at a fixed specificity of 90%. Analysis of the sequence motif surrounding the arginine methylation sites identified the 'RGG' motif, confirming previous reports ([Lischwe et al., 1985](#); [Kim et al., 1997](#)), while analysis of lysine methylation sites identified putative new sequence motifs, including the overrepresentation of leucine at the –1 position of mono-methyllysine. This method shows how in the absence of enzyme-specific data, different types of methylation could be used as a proxy for enzyme-specificity to enhance prediction performance.

Prediction of ubiquitination sites

Protein ubiquitination is catalyzed by the E1 activating enzyme, the E2 conjugating enzyme and the E3 ubiquitin ligase that mediates substrate specificity ([Amoutzias et al., 2012](#)). There are > 600 E3 ligases in human yet there is currently little information on the specificity of each E3 ligase ([Amoutzias et al., 2012](#)). Therefore, current prediction tools are based on global prediction of ubiquitination sites, as reviewed by [Chen et al. \(2014\)](#). [Nguyen et al. \(2015\)](#) used unsupervised clustering of the ubiquitination sites and developed a prediction model for each cluster. Analysis of sequence motifs for each of the clusters showed that each have varying sequence specificity, suggesting that clustering and motif analysis could be used to identify putative E3 ligase recognition motifs ([Nguyen et al., 2015](#)). [Nguyen et al. \(2017\)](#) later improved their prediction model by incorporating additional features, including amino acid composition, amino acid pairwise composition and a position-specific scoring matrix, into support vector machines (SVM). The SVM model for each cluster was combined into an ensemble model. This resulted in sensitivity of 67.6% and specificity of 58.8% from five-fold cross validation. Similar to protein methyltransferases and methylation, the E3 ligase-specificity for most ubiquitination sites are poorly defined. [Nguyen et al. \(2017\)](#) demonstrated that sequence-based clustering of ubiquitination sites, prior to training, could act as a viable proxy in the absence of enzyme-specific motifs. It is interesting to note that the same research group has also developed the UbiNet database of protein-protein interaction networks focusing on the interaction partners of the E1, E2 and E3 enzymes ([Nguyen et al., 2016](#)). This ubiquitination enzyme protein-protein interaction database, in conjunction with their prediction algorithm, could be used to explore the relationship between specific E3 ligases and their potential substrates.

What are the Biological Questions Explored Through the Prediction of PTMs?

As noted above, prediction of post-translational modifications involves the use of simple motif-driven methods, through to machine learning and/or artificial intelligence approaches, to identify and also characterize PTMs in the proteome. Whilst it is possible to generate a list of predicted PTMs, a major challenge is to analyze the list of predicted modification sites to generate valuable biological insights. Here, we will highlight three main biological questions that potential users of PTM prediction tools may like to address and provide rationale on why these questions are important. (1) Where are the modification site(s) and how do these relate to the structure and function of the protein? (2) What are the modification enzyme(s) responsible for writing or erasing a PTM at a specific amino acid within a protein? (3) What is the functional role of the PTM in the proteome? These three questions are complementary and depend on whether the analysis is focused on the modification enzymes, the protein substrates, or the specific type of modification.

Where are the Modification Site(s) and How do These Relate to the Structure and Function of the Protein?

After obtaining a list of modification sites from a PTM prediction tool, one subsequent step can involve mapping modifications to the structural features of the target protein. This helps understand how the modifications on a specific protein may affect its function. These analyses often involve the use of information from three-dimensional protein structures, along with predicted structural properties (e.g., domains, disordered regions) from protein sequence analysis tools.

When the three-dimensional structure of a modified protein is available, the modification site can be mapped onto structure. This can provide accurate information on surface accessibility of the modification site (Pang *et al.*, 2007) and, for enzymes, whether the modification is in the vicinity of active sites and may affect catalytic activity (Zanzoni *et al.*, 2011; Craveur *et al.*, 2014). Molecular dynamic simulations of modified proteins can be used to predict whether the modifications may cause conformational change (reviewed in Audagnotto and Dal Peraro, 2017).

Structures of protein complexes can provide information on whether modification sites are in the vicinity of protein-DNA, protein-RNA and protein-protein interaction interfaces and therefore have the potential to modulate interactions (Beltrao *et al.*, 2012). There are large variety of known protein-protein interfaces (Winter, 2006; Zhao *et al.*, 2011; Garma *et al.*, 2012) and these include two main types, domain-domain and domain-motif interactions, which have been well characterized in the literature (Stein and Aloy, 2010; Mosca *et al.*, 2014). Domain-domain interactions are often more stable interactions while domain-motif interactions tend to mediate transient interactions (Mosca *et al.*, 2014). The 3DID database systematically curates domain-domain or domain-motif interaction interfaces from known 3-D structures of protein complexes (Mosca *et al.*, 2014). Using the 3DID database, it is possible to determine whether PTM sites are present at or adjacent to the interface residues of an interaction domain or motif. This can help understand whether a PTM could possibly mediate or block a protein-protein interaction, and thus act as a protein interaction switch (Akiva *et al.*, 2012; Beltrao *et al.*, 2012; Van Roey *et al.*, 2012).

Modifications on critical sites of a protein can have important effects on signaling. A well-known example involves receptor tyrosine kinases where, upon ligand binding, there is autophosphorylation which leads to conformational changes and homo-dimerization (Ullrich and Schlessinger, 1990). These autophosphorylation sites have a variety of known functions, which include maintaining kinase activity in the absence of bound ligand by disrupting autoinhibitory interaction (Rosen *et al.*, 1983; Lemmon and Schlessinger, 2010) and modulating interaction with specific downstream substrates as part of signal transduction (Kazlauskas and Cooper, 1989; Arvidsson *et al.*, 1994; Hanke and Mann, 2009). Analysis of signaling proteins, such as receptor tyrosine kinases, may involve a multi-faceted and integrative approach, including but not limited to the application of tools and concepts discussed above.

What are the Enzyme(s) Responsible for Writing or Erasing a PTM on a Specific Amino Acid Within a Protein?

This question is applicable to PTMs that can be catalyzed by multiple enzymes. This enquiry is suited to researchers who are interested in the regulatory role of modifying enzymes and their effect on one target protein of interest. Knowing the specific upstream modifying enzymes would then, in turn, enable the researcher to perform further investigative experiments. This may involve verifying the activity of an enzyme through the absence or decreased abundance of the modification site upon perturbation of the enzyme through knockout (CRISPR) (Hamey *et al.*, 2017), knockdown (RNA inhibition) (Weiss *et al.*, 2007), or targeting with an inhibitor (Weiss *et al.*, 2007). Identifying the enzyme responsible for the modification site also enables us to contextualize the modified protein within an enzyme-substrate interaction network (Linding *et al.*, 2008; Erce *et al.*, 2012). This enables researchers to analyze the function of the modification enzyme, and one or more substrates, as a group, including identifying enriched canonical pathways, biological functions, sub-cellular localization and coordinated changes in PTM abundance under different cellular contexts (Linding *et al.*, 2008; Yang *et al.*, 2015).

What is the Functional Role of a PTM in the Proteome?

It is important to gain a general perspective on the function of each type of PTM in the proteome. Functional enrichment analysis of proteins which contain a specific PTM type might help to highlight the role of a PTM within the cell, including the biological pathways that are overrepresented in the modified proteins. These analyses could be performed using tools for Gene Ontology (GO) enrichment (Maere *et al.*, 2005; Grossmann *et al.*, 2007; Bindea *et al.*, 2009; Eden *et al.*, 2009; Reimand *et al.*, 2016; Mi *et al.*, 2017) and Pathway Analysis (Krämer *et al.*, 2014; Fabregat *et al.*, 2016). Different types of PTMs are associated with diverse biological functions. The best known examples include serine, threonine and tyrosine phosphorylation, which are often involved in signaling (Linding *et al.*, 2008). By contrast, lysine acetylation is frequently observed on proteins involved in energy metabolism (Choudhary *et al.*, 2014), arginine methylation is associated with RNA process and transport (Bedford and Clarke, 2009; Blanc and phane Richard, 2017), lysine methylation is enriched among protein translation machineries (Lanouette *et al.*, 2014) and fatty acid modifications are frequently present on membrane-bound proteins and receptors (Schwenk *et al.*, 2010). Among eukaryotes, protein glycosylation is associated with secreted proteins, proteins with extracellular domains and protein quality control (Benham, 2012; Xu and Ng, 2015). Interestingly, recent studies have also shown that glycosylation is also present among bacterial species (Szymanski and Wren, 2005; Lu *et al.*, 2015). This bacterial glycosylation has been suggested to modulate the function of virulence factors or factors involved in hijacking the host cellular machinery (Szymanski and Wren, 2005; Lu *et al.*, 2015).

Results and Discussion

Machine learning tools have a capacity to provide accurate predictions if the approach used to train, test and evaluate the tools are well-designed and the datasets are of high quality. However it must be acknowledged that PTM data remains sparse, will contain

a)

b)

false positives and also false negatives. Accordingly, it is important to highlight the challenges involved in dataset curation and how these could affect the performance of the prediction tools. Major factors to consider include the enzymes responsible for a modification site, and the size, quality, composition of the modification datasets.

Incorporating the site specificity of PTM enzymes is likely to improve the performance of predictive tools. Modifications known to arise from specific enzymes can be analyzed for particular sequence motifs using tools such as pLogo (O'Shea *et al.*, 2013). The existence of a sequence motif is a good indication that enzyme-specific prediction would improve prediction accuracy, and conversely that using all available data without considering enzyme-specificity in such cases would lead to worse prediction performance. As described above, enzyme-specific prediction improved predictions of phosphorylation (Song *et al.*, 2017) and acetylation (Deng *et al.*, 2016) sites. A downstream benefit of enzyme-specific prediction is the ability to better understand the specific function of each PTM-catalyzing enzyme. For example, GO enrichment analysis of kinase-specific substrates predicted by PhosphoPredict show that while all kinase families were significantly enriched among diverse biological pathways, channel activity and ion channel activity were significantly overrepresented among MAPK only.

The taxonomic relevance of each enzyme should be considered when using enzyme-specific PTM prediction. For example, *S. cerevisiae* has three relevant acetyltransferases (HAT1, KAT2A and KAT6), and therefore predictions made by GPS-PAIL for other acetyltransferases should not be used for yeast (Deng *et al.*, 2016). However, in cases where a PTM is highly conserved across cellular organisms, such as N-glycosylation (Deshpande *et al.*, 2008; Aebi, 2013; Jarrell *et al.*, 2014; Pinho and Reis, 2015; Strasser, 2016), many enzymes may be conserved and taxonomic filters may be less useful (Beltrao *et al.*, 2013). Most enzyme-specific PTM data are focused on human and a few model organisms such as yeast. Databases that specialize in one type of PTM often include annotation for enzyme specificity. For example, both Phospho.ELM (Dinkel *et al.*, 2011) and PhosphoSitePlus (Hornbeck *et al.*, 2015) curates phosphorylation sites and include annotation for kinase-specific sites.

An adequate number of PTM sites in the training datasets are necessary for the machine learning algorithms to detect reliable patterns from the data and to use these patterns for predictions. However, it is difficult to know what actually represents an adequate number. It is important for tools to report the number of positive modification sites and negative sites considered, such that users can evaluate tools based on the size of the datasets. However there remains a strong possibility of false negatives being present and used. False negatives could be present due to a number of reasons, including difficulties in detecting low abundance proteins (Picotti *et al.*, 2009) or low stoichiometry modification sites (Amoutzias *et al.*, 2012) and challenges in the analysis of some membrane proteins, which are difficult to solubilize for analysis with mass spectrometry (Barrera and Robinson, 2011). To increase the coverage of the training datasets and to mitigate the effect of false negatives, data can be combined from multiple sources, including publically available PTM databases and those curated from literature. There are a number of publically available PTM databases, including Uniprot (Bateman *et al.*, 2017) and dbPTM (Huang *et al.*, 2016), which could be used for building collections of modification sites. However, there will typically be inconsistencies between different large-scale PTM resources which are difficult to reconcile.

Similar to false negatives, there are likely to be false positive modifications in experimental data and, when used for a tool's training set, these could lead to decreased prediction accuracy and specificity. This problem could be mitigated by filtering experimental data with a stringent false discovery rate (FDR), or selecting only modification sites which are verified by two or more independent experiments (Amoutzias *et al.*, 2012). Recently, Hart-Smith *et al.* (2016) showed that large-scale mass spectrometry analysis of protein methylation sites are subjected to high FDR. The reason is that many types of amino acid substitutions are isobaric to the mass change associated with a methyl group, and in many cases, it is not possible to distinguish between them. The study also highlighted that a target-decoy approach is ineffective for controlling for the FDR of protein methylation sites. Heavy methyl-group labelling through Stable Isotope Labelling with Amino Acid in Cell Culture (SILAC) was suggested as the validation criteria required for methylation sites identification. The MethylQuant tool (Tay *et al.*, 2017a,b) was recently developed to support heavy-methyl SILAC analyses. The above highlights the importance of using high quality experimental datasets, such as those that uses SILAC for methylation site identification, to avoid inclusion of false positive sites.

The ideal training and testing datasets should contain an equal proportion of positive and negative PTM site data. Yet there are often more unmodified than modified sites. One common solution is to train multiple machine learning models, e.g. an ensemble approach, each time using a random subset of the negative sites and averaging results from many models to increase prediction performance (Yang *et al.*, 2015). A further problem with modification datasets is the presence of inspection bias. For example,

Fig. 4 Visualization of modified proteins, protein-protein interactions, and enzyme-substrate interactions in *S. cerevisiae* using the PTMOracle app in Cytoscape. Each protein is represented as a node in the network. The pie chart for each protein represents the proportion of known modification sites that are phosphorylation (red), acetylation (blue) and methylation (grey). Protein-protein interactions are represented by thin grey lines, kinase-substrate interactions are represented by thick red arrows, acetyltransferase-substrate interactions are represented by thick blue arrows and methyltransferase-substrate interactions are represented by thick grey arrows. All enzyme-substrate interactions are directional, with the arrow indicating the substrate. (a) The interactions between histone proteins are shown in the network. The network focuses on the enzyme-substrate interactions that target histone proteins Hht1p and Hht2p (large nodes), and a subset of non-histone interaction partners for these two histone proteins are also shown. Hht1p is phosphorylated, acetylated and methylated, and the enzymes which catalyze these modifications are known and shown. Unlike Hht1p, the enzymes which are responsible for the phosphorylation, acetylation and methylation of Hht2p have not yet been experimentally identified. The methyltransferases Set1p, Set2p, and Dot1p form protein-protein interactions with Hht1p, predicting that these methyltransferases catalyze Hht1p methylation. (b) The protein-protein interaction network focusing on Npl3p and Yra1p (large nodes). The enzymes responsible for Npl3p methylation and phosphorylation are known and shown (arrows). The methyltransferase Hmt1p interacts with the methylated protein Nab2p, suggesting that it is responsible for Nab2p methylation. In contrast, the methyltransferase responsible for the methylation of Yra1p has not been confirmed, and Yra1p is not known to bind any existing protein modifying enzymes.

histone protein is the most extensively analyzed protein for protein methylation sites (Lothrop *et al.*, 2013) and there will likely be a high number of histone proteins in any methylation sites training set. This may potentially lead to bias. This could be resolved by identifying redundant protein sequences and redundant modification sites from the dataset, using tools such as CD-HIT (Huang *et al.*, 2010) and keeping only one representative example from each group of homologous sites (for example, Deng *et al.*, 2017; Nguyen *et al.*, 2017).

Future Directions

There remains scope for the improvement of PTM site prediction. Since functionally important modification sites are more likely to be evolutionarily conserved, others have used this as a means to rank and prioritize predicted PTM sites. Beltrao *et al.* (2012) developed the PTMfunc database which predicts the functional relevance of phosphorylation, acetylation and ubiquitination sites for 11 eukaryotic organisms. The PTM sites that are evolutionarily conserved are more likely to be biologically important. Users of PTM prediction tools could query the PTMcode database developed by Minguéz *et al.* (2012) to identify single or pairs of co-evolving sites that are within the same domain or motifs sequences, thus highlighting putative important residues within domains or motifs, or co-evolving sites between a interacting proteins. This would help predict putative sites of greatest functional importance.

Downstream, it is important to decipher how PTMs regulate the dynamics of biological networks and participate in protein ‘interaction codes’ (Winter *et al.*, 2014). Bioinformatic tools are emerging that enable users to investigate cross-talk between PTMs, and explore enzyme-substrate relationships in the context of the interactome. Tay *et al.* (2017a,b) developed the PTMOracle app for the Cytoscape network software platform. This tool enables users to generate pie charts for each node in the network to represent the proportion of different types of PTMs on the protein (Fig. 4). More importantly, the tool can co-map and co-analyze PTMs, enzyme-substrate relationships along with other protein-protein interactions, and to generate and visualize a series of complex queries involving protein structural data, domains, motifs and interactions. Whilst the PTMOracle tool currently only uses known PTM sites in its underlying databases, predicted PTMs could also be used to enrich the networks generated and to help develop new hypotheses about PTM and protein function.

Closing Remarks

In conclusion, this article has highlighted several critical factors for developing robust and reliable PTM prediction tools. These factors include careful curation of PTM datasets, the use of enzyme-specific modification sites for tool training datasets, and the use of feature selection tools to identify non-redundant sets of features. We also discussed the biological questions that could be explored when analyzing a list of predicted PTMs. These questions include how a PTM relates to the structure and functions of the protein, the effect of PTMs on protein-protein interactions, the binding specificity of the modification enzymes and the biological processes that they regulate, and the function of different types of PTMs. It is hoped that these factors, together, will inspire the development of novel bioinformatics tools, to decipher the function of PTMs and to illuminate the roles of PTMs in protein-protein ‘interaction codes’.

Acknowledgements

MRW acknowledges support from NCRIS, administered by Bioplatforms Australia, and from the New South Wales State Government RAAP Scheme. We thank Aidan Tay for kindly providing the figure that illustrates PTMOracle and Daniel Winter for kindly providing the figures that illustrate the chemical structures of modified amino acids.

Biographical Sketch

Dr. Chi Nam Ignatius Pang is a research associate currently working with Prof Wilkins. He completed his PhD in 2010 on the topic "The Dynamics of Protein Interaction Networks." In his thesis, he explored different mechanisms that govern the dynamics of protein-protein interactions – such as how changes in domain-domain interactions, post-translational modifications, and protein abundance can dynamically switch on/off protein-protein interactions. He also performed a large-scale screen of arginine and lysine methylation in the yeast proteome, and found that there are more methylated proteins than previously thought. In collaboration with Dr. Gene Hart-Smith, he is currently investigating how protein methylation affects protein-protein interactions. This involve identifying changes in protein complexes between wild type yeasts and methyltransferase knockout mutants using protein correlation profiling. Prior to his postdoc he had 2 years of experience in finance involving data analytics and fraud detection.

Prof Marc Wilkins is the Director of the Initiative. Professor Wilkins holds the chair of Systems Biology in the School of Biotechnology and Biomolecular Sciences. His research interests involve the proteomics of protein-protein interactions and systems biology. Specifically, Professor Wilkins' research focuses on the dynamics of protein-protein interaction networks, and the role that gene expression and protein post-translational modifications play in the control of protein interactions and thus delivery of cellular function in yeast and human cells.

Protein Properties

Kentaro Tomii, Artificial Intelligent Research Center (AIRC), National Institute of Advanced Industrial Science and Technology (AIST), Tokyo, Japan

Introduction

Protein molecules, the main constituents of living things, are organic compounds consisting mainly of carbon, nitrogen, oxygen, hydrogen, and sulfur. Protein behavior such as dynamics and interactions depends on the protein's physicochemical properties, even when a protein performs complex and exquisite roles *in vivo*. Therefore, knowing protein properties is expected to be useful for analyzing and understanding proteins.

A protein possesses its own unique properties to perform its function. Proteins are classifiable roughly into four types: globular proteins, membrane proteins, fibrous proteins, and intrinsically disordered proteins. Protein properties differ depending on the protein type. For instance, most membrane proteins show higher hydrophobicity than proteins of other types. This nature is strongly associated with their roles in a cell, i.e., the manner in which they localize and work at membranes. This characteristic, which is related to the protein solubility and other properties, is also useful to classify them using computational methods as introduced in the section below, although proteins of different types can be fused. For instance, a protein can have soluble domain(s) and transmembrane domain(s), or can have soluble domain(s) and intrinsically disordered regions. The function of the entire protein is based on the properties of individual domains.

Various properties of proteins or protein domains can be measured using physicochemical and biochemical experiments. However, indeed, precise measurements cannot be obtained easily. Therefore, conducting research on an unknown protein is expected to be effective to ascertain the approximate values of various protein properties using computational methods. This article briefly introduces widely various *in silico* methods and tools used for predicting and calculating protein properties such as molecular weight, isoelectric point, solubility, crystallizability, and hydrophobicity.

Amino Acids

A protein is a string of amino acids. The arrangement of that string (primary structure) determines a protein's structure and function. That is to say, amino acid properties are the origin of the structure, function (and also evolution) of proteins. In general, naturally occurring proteins comprise the 20 most common amino acids with different side-chains. Each type of amino acid possesses unique properties that affect the structure and function of proteins, depending on its side-chains. Based on the chemical properties of side-chains, the 20 amino acids are classified roughly into four groups: hydrophobic, polar, and charged residues, and Gly which only has H (hydrogen) as its side-chain. Already, numerous physicochemical and biochemical properties of amino acids have been measured and published.

A compendium of such properties is available. Based on the 188 amino acid properties collected and analyzed by Kidera and his colleagues (Kidera *et al.*, 1985), Nakai *et al.* (1988) launched the so-called AAindex database, which includes 222 amino acid indices: sets of 20 numerical values representing their various properties. Since then, the database has been developed and expanded. In 1996, Tomii and Kanehisa (1996) reformatted the database and released a collection of 402 amino acid indices, with a list of similar indices having correlation coefficients of 0.8 (– 0.8) or more (less), and 42 amino acid substitution matrices representing similarity between amino acids. In a substitution matrix, higher (better) scores are assigned to pairs of residues with more similar properties. They are used for protein sequence analysis such as similarity search and phylogenetic inference. The ever-growing database currently (AAindex Release 9.2) contains 566 indices, 94 matrices, and 47 contact potentials (Kawashima *et al.*, 2008). The AAindex database is available at “see Relevant Websites section”. According to the result of cluster analysis, most of the collected indices are roughly classified into several classes according to characteristics such as hydrophobicity, propensities related to secondary structures, volumes of amino acids, and amino acid composition.

ExPASy offers a tool called ProtScale to visualize a profile as a two-dimensional plot for a protein using 57 indices at “see Relevant Websites section” (Gasteiger *et al.*, 2005). EMBOSS also provides a program called pepwindow via the web browser interface (see “Relevant Websites section”) and Web Services, for drawing a hydropathy plot for a protein based on the hydropathy index (Fig. 1) proposed in an earlier report (Kyte and Doolittle, 1982). It can also be used to draw various plots using various indices by substituting the index in ‘datafile’.

Amino Acid Composition and Molecular Weight

As described above, naturally occurring proteins consist mainly of 20 types of amino acids. The 20 most common amino acids are known to be used unevenly. The frequency of use of individual amino acids is biased. On average, frequently occurring residues such as Ala and Leu account for approximately 9%, although rare residues such as Cys and Trp account for about 1%. Proteins are roughly classified into four types: water-soluble globular proteins, membrane proteins, fibrous proteins, and intrinsically disordered proteins. Amino acid compositions for those four types of proteins differ (see below). As one might expect, they differ for individual proteins. Especially, fibrous proteins such as collagen consist of a characteristic repeat such as Gly Pro-X and Gly X-hydroxyproline, which is a modified proline residue.

Fig. 1 The AAindex entry of the hydropathy index proposed by Kyte and Doolittle. Each entry in AAindex includes its accession number (denoted as 'H'), the name or short description of the index ('D'), the PubMed ID of literature which publishes the index ('R'), the author name(s) ('A'), the title of the literature ('T'), the bibliographic information of the literature ('J'), the list of similar indices and their correlation coefficients with the index ('C'), the index value for each amino acid ('I'), and the termination symbol ('//').

It is often argued that amino acid composition is associated with structural and biological characteristics of proteins. Actually, chain-length (=domain size) dependence of amino acid composition is also known to exist (White, 1992; Carugo, 2008). Therefore, many computational prediction methods have been proposed, such as the molar extinction coefficient, solubility and crystallizability of proteins, for folding types, structural classes, secondary structure contents, quaternary structural types, and subcellular localization, and for membrane proteins, thermophilic proteins, disordered proteins, based on amino acid and/or dipeptide composition.

A protein's molecular weight is the total of the molecular weights of the protein's constituent amino acids, in addition to the weights originated from posttranslational modifications. Knowing the molecular weight of a protein is helpful for setting and selecting methods for expression and purification systems of it. Although the molecular weight of a protein can be ascertained using analytical biochemistry, exact measurements are quite laborious. At present, as the genome sequences are accumulated, the molecular weights of constituent amino acids are often used to calculate the total by converting the decoded nucleotide sequence into an amino acid sequence. In doing so, it is noteworthy that the molecular weight of the water molecules desorbed along with peptide bond formation is subtracted from the sum of the constituent amino acid molecular weights of the proteins.

Isoelectric Point

Proteins contain ionizable residues including both acidic (aspartic acid and glutamic acid) and basic (arginine, lysine, and histidine) residues. "The isoelectric point (pI) is defined as the level of pH at which the protein/peptide has a net charge of zero

(Smoluch *et al.*, 2016)". Proteins show different pI depending on the type and number of constituent amino acids. For instance, pI of a protein such as aldolase is around 10, although the pI of a protein such as ornithine decarboxylase is around 4 (Dice and Goldberg, 1975). In proteomes, the distribution of pI values of proteins has been known to show a generally bimodal distribution. It has a low fraction of proteins with pI close to 7.4, which closely approximates the pH of the major compartments inside of most cells. A report of one study describes the relation between the length of proteins and their pI values (Kiraga *et al.*, 2007). It might have different charge states depending primarily on the surface charge and solution state. At the pI of a protein, as attractions between protein molecules are maximized, its solubility is minimized. Using such a difference in pI, proteins are separable. Therefore, it is important to calculate pI for each protein. Actually, the pI of a protein is calculable approximately from the protein's amino acid composition. However, generally, it is difficult to obtain the exact value of pI without experimental research.

Generally speaking, although accurate calculation is not easy, various approximate calculation methods have been proposed to estimate the pI of a protein. In brief, the pI of a protein is calculated based on pKa, the inverse logarithm of an acid dissociation constant, of charged residues. Many sets of pKa values for the ionizable groups of seven charged residues (Cys, Asp, Glu, His, Lys, Arg, and Tyr) have been published along with the terminal groups: amino and carboxyl groups. Recently, an isoelectric point calculator, called IPC (see "Relevant Websites section"), has been proposed based on the optimized sets of pKa values using a basin-hopping procedure (Kozłowski, 2016). To develop accurate methods for structure-based calculation of pKa values, a blind prediction challenge was organized: The pKa Cooperative (see "Relevant Websites section"). For this challenge, invited research groups have attempted to predict an unpublished set of experimental pKa values, especially for interior residues in proteins (Nielsen *et al.*, 2011). Actually, pKa calculations for those residues can be difficult.

The pI values of proteins can provide useful information to advance protein science. One report has described that "a relationship exists between a protein's pI and the pH under which it will crystallize" (Kirkwood *et al.*, 2015). One report describes that mammalian complexes of three or more unique proteins have greater homogeneity than the expected values in terms of predicted pI values (Wong *et al.*, 2008).

Solubility and Crystallizability

The solubility of proteins in aqueous solution is regarded as dependent mainly on the surface structure of proteins and the types of amino acids on their surfaces. Generally, proteins with more charged and polar residues on their accessible surface with water molecules show higher solubility. Therefore, the optimum pH differs for each protein. The solubility of a protein also depends on the salt concentration of the solution and the type of salt. Proteins such as membrane proteins, with many hydrophobic residues on their surface, are insoluble in most cases, although they can be solubilized in some cases using surfactants.

Early computational methods for protein solubility prediction from its sequence were simple and were based on the rate of charged residues contained in a protein. In recent years, with the progress of the structural genomics projects worldwide, large amounts of data related to the expression system of many proteins and their results have been accumulated. Therefore, most current prediction methods use such huge datasets as learning datasets. Furthermore, they are based on machine learning methods, which makes it possible to use not only the rate of charged residues but also various physicochemical properties such as those in AAindex for solubility prediction. The prediction accuracy has improved as a consequence. A useful interpretation and list of solubility prediction methods for protein production in *Escherichia coli* are available in a recent review (Chang *et al.*, 2014).

X-ray crystallographic analyses still play a major role in protein tertiary structural studies. About 90% of entries containing proteins in PDB were determined using X-ray crystallography as of December 2017. In X-ray crystallography, obtaining diffraction quality crystals of proteins is a central issue. As is the case with solubility prediction, prediction methods for protein crystallization have been developed for and along with the development of structural genomics projects. For advancing structural genomics projects, it is indispensable to select good target proteins and to search optimal crystallization conditions. Like solubility prediction methods, as structural genomics projects progress, large amounts of data related to protein crystallization are becoming available, leading to a vigorous construction of prediction methods using such huge data and machine learning methods. For these reasons, crystallization prediction methods have progressed in recent years by consideration of various protein characteristics related to their crystallization, although it remains controversial, which is the influential factor for protein crystallizability. An exhaustive and practical review of prediction for protein crystallizability has been published (Smiałowski and Wong, 2016).

Hydrophobicity

Proteins usually include hydrophobic residues as well as charged and polar residues. The proportion of hydrophobic residues in a protein is useful for classifying proteins because membrane proteins tend to have more hydrophobic residues in their trans-membrane region(s) than other proteins do. For instance, a GRAVY (GRand AVerage of hydropathY) score, which is calculated by summing the hydropathy values of all the amino acids and by dividing by the number of residues in a protein, has been developed and used for predicting membrane proteins (Kyte and Doolittle, 1982).

Because hydrophilicity and hydrophobicity are two sides of the same coin, Kyte and Doolittle used the term 'hydropathy', which means "strong feelings about water." They originally proposed their hydropathy index based on both the water-vapor transfer free energies and the interior–exterior distribution of the side-chains. Recently, an engineering measurement, contact angles of a water nanodroplet on a(n artificial) planar surface (of peptides), has been used for characterizing hydrophobicity of amino acids

(Zhu *et al.*, 2016). Including these, many different scales for representing hydrophobicity of amino acids have been published to date (Simm *et al.*, 2016). The variation of hydrophobicity scales can be attributed to their underlying formulations. A prominent difference is the way of dealing with amino acids. For instance, Cys residues can be hydrophobic when we consider their locations in proteins, although their hydrophilic nature emerges when we consider individual free amino acids.

Disordered Proteins

Soluble globular proteins, membrane proteins, and fibrous proteins must possess unique tertiary structures under physiological conditions to perform their functions. However, it is considered that intrinsically disordered proteins (IDPs) do not possess unique tertiary structures but instead exist as dynamic structural ensembles, although they have specific structures when they bind to other molecules under physiological conditions. Most IDPs are involved in important roles in cellular signalling and regulation. Many nucleic proteins are known to contain IDPs. Actually, it is considered that about 20%–30% of eukaryotic proteins are IDPs. Intrinsically disordered proteins (or regions) tend to have more abundant Gly, Ser, and Pro residues, and less hydrophobic residues than other proteins (or regions). Elucidating intrinsically disordered regions in a protein is helpful to ascertain the boundaries of protein domains suitable for X-ray crystallographic analysis. Numerous IDP (or region) prediction methods using this tendency and other features have been reported. A comprehensive summary of methods and databases for disorder prediction is available (Lieutaud *et al.*, 2016). Because IDP prediction can reflect difficulties of discrimination between ordered and disordered proteins (or regions) and because more information about IDPs has been accumulated than ever, machine learning methods such as support vector machine (SVM) and artificial neural network (ANN) have been applied for this purpose.

Quaternary Structure

A complex composed of multiple protein chains (subunits) is defined as a quaternary structure, also called a multimer, or biological assembly. Many proteins form their quaternary structures when they function *in vivo*. The quaternary structure of a protein can be ascertained by physicochemical and biochemical studies. However, accurate measurements are generally elaborate, and exhaustive measurements of protein quaternary structures are not easy. Actually, the estimated state(s) of protein quaternary structure measured in solution, those described by the author(s) in PDB, and the states estimated based on analysis of contacts between protein chains in the crystal in PDB are often different. Under these circumstances, development of an accurate method for estimating the quaternary structure of proteins is expected. However, even among homologous proteins, the quaternary structure of proteins is often not conserved as much as its three-dimensional structure is, and in not as many cases. However, even between distantly related proteins, predictions using the quaternary structure of homologous proteins can be effective in some cases (Nakamura *et al.*, 2017).

Useful Resources

Below, we introduce and summarize useful sites and tools other than those introduced into the papers and reviews described above.

Closing Remarks

Elucidation of protein properties is important and helpful for advancing protein research. Many computational methods for the broad range of protein properties have been developed and have been made available, especially along with the development of structural genomics projects as described above. These methods are expected to become more helpful and reliable for our research, according to their improvement and the accumulation of related data.

The Evolution of Protein Family Databases

Introduction

Elucidation of protein function forms a major part of understanding fundamental natural processes, including the basis of diseases and the interaction of species with their environments. Characterising protein function using laboratory-based experiments is a high-cost, low-throughput process that cannot keep pace with the volumes of data being generated by genomic and environmental sequencing projects. The problem has become particularly acute in recent years, as sequencing technology has developed to the point where it is possible to sequence entire genomes, or to generate hundreds of millions of DNA sequences from environmental samples, in a single experiment. The pace of data generation now outstrips the rate of experimental characterisation by many orders of magnitude, and the disparity is likely to get worse as sequencing technologies improve. For the custodians of the data, charged with the task of assigning functions to the mass of raw sequences, the deluge has created almost unimaginable annotation burdens. To give an example, during the last 30 years, dedicated teams of curators have manually annotated ~555,000 UniProtKB/Swiss-Prot sequences; this figure is roughly equal to the number of sequences now entering UniProtKB per week. To put these figures in context, the European Bioinformatics Institute Metagenomics peptide database now contains almost 50 million sequences, derived from 400 data-sets ([Mitchell et al., 2017](#)). More than 15 million of these are predicted to be full length, but only ~1 million currently have counterparts in UniProtKB; and the database is expected to grow to 100s of millions or billions of sequences as proteins continue to be assimilated. The future implications for resources like UniProt ([UniProt Consortium, 2017](#)) are staggering. Inevitably, this impossible situation has mandated the use of computational approaches to complement and mitigate curators' Herculean annotation tasks.

Before the situation became as acute as it is today, an innovative strategy to try to address the problem focused on the use of protein family databases. Such databases have been part of the ecosystem of bioinformatics tools and resources for almost 30 years. Underpinned by information derived from multiple sequence alignments, they offer a more sensitive and *scalable* alternative to pairwise sequence analysis approaches (e.g., such as BLAST ([Altschul et al., 1990](#))) that compare a query sequence against all proteins in a target database (consider, for example, that Tara Oceans scientists have estimated that a BLASTx comparison of ~120 million of their eukaryotic sequences against UniRef90 (containing ~26 million sequences) and the many millions of sequences in the Marine Microbial Eukaryote Transcriptome Sequencing Project (MMETSP; [Keeling et al., 2014](#)) would require ~9 million CPU hours on a high-performance computing facility). Nevertheless, the pivotal role that protein family databases now play in sequence analysis is probably under-appreciated: today, much of their work is conducted behind the scenes in support of the principal players – the primary sequence repositories, like UniProtKB.

The origins of protein family databases can be traced to a description – in *Of URFs and ORFs* ([Doolittle, 1986](#)) – of short amino acid 'patterns' that often characterise specific functional sites. In his book, Doolittle asserted that such patterns could be grouped and potentially used to search for similar sites in query sequences. Reading this inspired Bairoch (then a postgraduate student in Geneva working on developing the Swiss-Prot database) to write a program to do just this – he called the program PROSITE ([Bairoch, 2000](#)). At the same time, he scoured the literature for other sequence patterns, but was dismayed to discover that there were few of them; and those he did find weren't sufficiently diagnostic to be useful ([Bairoch, 2000](#)). He therefore decided to create some patterns of his own. In the sections that follow, we explore how Bairoch's pioneering work spawned the creation of numerous protein family databases, and how these became such critical tools for sequence annotation.

Protein Family Classification – Different Approaches

PROSITE

Seeking to create a collection of his own diagnostic 'signatures', Bairoch began by developing short patterns for various binding sites, active sites, sites of post-translational modification, etc. and/or particular family groupings. The process involved creating multiple alignments of representative sequences, inspecting the alignments for conserved residues, or residue groups, and then encoding the observed pattern of conservation in a regular expression-like syntax that would, ideally, provide a consensus for all sequences in the family or sharing the functional site. Importantly, for each, he provided a detailed abstract describing the biological entity (site, domain, family, etc.) encompassed by the expression. The first collection of these patterns – 58 in all – was bundled with the PROSITE search tool and released in March 1988 as part of the PC/Gene software package, which was then being commercialised by IntelliGenetics.

At the time, PROSITE was very useful for diagnosing potential functional sites in individual sequences and/or for suggesting their likely family relationships; but it was also becoming clear that the resource had a much larger role in characterising entire sequence collections, such as those represented by Swiss-Prot ([Bairoch and Boeckmann, 1991](#)). Hence, before long, Bairoch was

Table 1 Sample of some of the first sequence patterns released in PROSITE

Pattern and documentation IDs	Functional site	Sequence Pattern ^a	Pattern length
PS00001; PDOC00001	*N-glycosylation site	N-[P]-[ST]-[P]	4
PS00004; PDOC00004	*cAMP- and cGMP-dependent protein kinase phosphorylation site	[RK](2)-x-[ST]	4
PS00005; PDOC00005	*Protein kinase C phosphorylation site	[ST]-x-[RK]	3
PS00006; PDOC00006	*Casein kinase II phosphorylation site	[ST]-x(2)-[DE]	4
PS00007; PDOC00007	*Tyrosine kinase phosphorylation site	[RK]-x(2,3)-[DE]-x(3)-Y	8–9
PS00008; PDOC00008	*N-myristoylation site	G-[EDRKHPFYW]-x(2)-[STAGCN]-[P]	6
PS00009; PDOC00009	*Amidation site	x-G-[RK]-[RK]	4
PS00010; PDOC00010	Aspartic acid and asparagine hydroxylation site	C-x-[DN]-x(4)-[FY]-x-C-x-C	12
PS00011; PDOC00011	Vitamin K-dependent carboxylation domain	E-x(2)-[ERK]-E-x-C-x(6)-[EDR]-x(10,11)-[FYA]-[YW]	26–27
PS00012; PDOC00012	Phosphopantetheine attachment site	[DEQGSTALMKRH]-[LIVMFYSTAC]-[GNQ]-[LIVMFYAG]- [DNEKHS]-S-[LIVMST]-[PCFY]-[STAGCPQLIVMF]- [LIVMATN]-[DENQGTAKRHLM]-[LIVMWSTA]- [LIVGSTACR]-[LPIY]-[IVY]-[LIVMFA]	16

^aWithin these expressions, amino acid residues (denoted using the IUPAC single-letter notation) in square brackets are allowed at that position; those in curly brackets are forbidden at that position; x is a wild-card, denoting any amino acid; numbers in parentheses indicate how many times a residue, or residue group, can occur; and a residue on its own is strictly conserved.

Note: Asterisks denote patterns that have been shown to exhibit poor diagnostic performance.

under pressure to liberate PROSITE from its commercial shackles. Accordingly, in October 1989, he announced that he was making the resource publicly available, and released a new version (4.0) the following month, with 202 entries. **Table 1** shows some of the first patterns collected in PROSITE (Bairoch, 1991).

The first thing to notice in **Table 1** is that most of the expressions are very short and, in a sense, quite ‘primitive’ – some are just 3 or 4 residues long. In the late 1980s, when sequence databases were still relatively small (by comparison with the vast, genome-scale repositories of today), these and other PROSITE patterns were nevertheless quite useful indicators of potential functional sites or family relationships. However, the shorter a pattern and the more variable it is (i.e., the larger the allowed residue groups and the more wild-cards used), the poorer its diagnostic performance. Inevitably, as target sequence databases grew larger, this was to become increasingly problematic.

In 1994, the diagnostic performance of then current PROSITE patterns was analysed statistically with respect to Swiss-Prot 30.0 and to a randomised database derived from it by regional shuffling. The frequency of occurrence of the patterns depicted in **Table 1** is shown in **Table 2**. As can be seen, the most promiscuous patterns are those that are shortest and most variable. In fact, patterns PS00001 to PS00009 are so noisy that they’re flagged as ‘patterns with a high probability of occurrence’ (this flag allows such promiscuous matchers to be ignored by modern PROSITE-scanning tools).

Interestingly, in **Table 1**, pattern identifiers (IDs) PS00002 and PS00003 are missing; the latter is also missing from **Table 2**. PS00002 encoded a glycosaminoglycan attachment site (S-G-x-G); this expression was qualified by an additional condition that there should be at least two acidic amino acids from –2 to –4 relative to the serine attachment site. Similarly, PS00003 encoded a tyrosine sulphation site, the consensus features of which were described in terms of the acidic, hydrophobic and polar residues within 1 and 7 residues N- and C-terminally to the tyrosine (specifically, E or D within two residues of the Y (typically at –1); at least three acidic residues from –5 to +5; no more than 1 basic residue and 3 hydrophobic from –5 to +5; at least one P or G from –7 to –2 and from +1 to +7; or at least two or three D, S or N from –7 to +7; absence of disulphide-bonded C residues from –7 to +7; and absence of N-linked glycans near the Y).

In early PROSITE releases, PS00002 and PS00003 were termed ‘rules’. Rules were logical natural-language assertions used to complement or replace patterns that couldn’t be described effectively by the formal consensus-expression syntax. Being written in free-text English, the only way to scan rules against a sequence database was to encode them directly inside the search program; many of the earliest PROSITE-scanning tools were unable to do this (Gattiker *et al.*, 2002).

As the mass of accumulating protein sequences grew, and their diversity widened, the diagnostic power of several PROSITE entries began to erode. Some of these were revised and updated in light of knowledge derived from new family members in Swiss-Prot (see **Table 3**); PS00002, PS00003 and other poorly performing rules and patterns were deleted. However, from the outset, the considerable divergence of some protein families (e.g., globins, immunoglobulins, heat-shock proteins), functional sites and domains (SH2, SH3, PH, Kringle domains, etc.) couldn’t be encapsulated efficiently using sequence patterns. Part of the problem is

Table 2 Pattern frequencies based on Swiss-Prot 30.0 and the corresponding PROSITE release. Patterns PS00001 to PS00009, which are the shortest and most variable, are the most promiscuous

Pattern		Swiss-Prot 30.0		Randomised		Exp. hits	Quota
ID	Length	Matches	Sequences	Matches	Sequences	/1000 res.	%
PS00001	4	79,458	25,162	74,272	25,707	5.25E + 00	93.47

Note: To keep pace with the growth of Swiss-Prot, successive updates aimed to maximise the number of true-positive matches, and minimise the number of false-positives (FP) and missed true sequences (FN). Inevitably, attempts to accommodate the family's sequence diversity led the pattern to become less selective over time. The Arg residue, implicated in G protein coupling, is highlighted.

that matching a consensus expression is a binary event: i.e., a sequence either matches exactly, or not at all. Diagnostically, this approach is very brittle. Efforts to capture highly divergent sequence groups in this way tend to result in patterns that are either too permissive (i.e., make significant numbers of erroneous (false-positive) matches), or too selective (i.e., fail to match significant numbers of genuine family members – false negatives). Attempting to address this problem, two parallel initiatives emerged, complementing some of the diagnostic limitations of patterns and rules with more sophisticated pattern-recognition techniques: these were 'profiles' (Bairoch and Bucher, 1994) and protein 'fingerprints' (Attwood and Beck, 1994).

PROSITE's Profile Library

Profiles (or position-specific weight matrices) are tables of amino acid weights and gap penalties used to compute a similarity score, relative to a pre-defined cut-off value, when aligned with a protein sequence. They were introduced into PROSITE 12.0, in June 1994. The data structure used was a generalisation of that originally described by Gribskov and colleagues (Gribskov *et al.*, 1987, 1990), and modified by Lüthy and co-workers (Lüthy *et al.*, 1994).

Like patterns, profiles are built from sequence alignments; however, they are more tolerant of amino acid changes and of sequence length differences arising from insertions or deletions. In principle, this allows relationships between sequences to be modelled more 'realistically'. One advantage of this is that, by contrast with the specificity of patterns (which focus on short, highly similar regions), profiles can be used to characterise the full length of sequence alignments, whether they encode family-specific groups or family-agnostic domains. Consequently, by design, profiles can encapsulate both conserved and divergent regions. This gives rise to the possibility of unrelated sequences achieving significant scores with partially incorrect alignments. This situation is

mitigated to some extent by the requirement that, in order to be accepted as a true match, a sequence must align correctly with residues known to have particular structural or functional properties (metal-ion binding, catalysis, protein-protein interaction, etc.) as verified by experimental data (Bairoch and Bucher, 1994). Part of a profile is shown in Fig. 1, illustrating the complexity of the scoring system relative to the simplicity of the consensus expressions in Table 1.

Broadly speaking, a profile is a scoring 'matrix' (the elements of which are denoted MA in Fig. 1) containing an alternating sequence of position-specific scores. When a sequence is aligned with a profile, its overall similarity score is derived by summing the scorable components, or 'states': specifically, the 'beginning' (B), 'match' (M), 'insert' (I), 'delete' (D) and 'end' (E) states. In addition, so-called 'state-transition' steps between consecutive positions are also scored: 16 state-transition scores, including transitions between identical states, are defined for all possible transitions between the set of states [B,M,I,D] and [M,I,D,E]: BI, BD, MI, MD, IM, etc. (state-transition scores are analogous to gap-opening penalties used in alignment algorithms).

Fig. 1 Example profile showing position-specific and state-transition scores for rhodopsin-like GPCRs. The 'ALPHABET' and 'LENGTH' parameters indicate that the profile spans a 259-residue portion of the protein. All true-positive (T) and partial (P) matches are listed in the database cross-references (DR); links to structures in the PDB (Rose *et al.*, 2017) are made in the 3D lines. The profile's diagnostic performance is shown in the numerical results (NR).

Fig. 1 shows excerpts from the PROSITE profile for rhodopsin-like GPCRs (G_PROTEIN_RECEP_F1_2, PS50262). Of particular interest is the profile's diagnostic power, encoded in the NR lines. These reveal that the profile statistics were derived from a search of UniProtKB/Swiss-Prot 2017_08, which contained 555,426 sequences. The profile made 2510 matches in 2508 sequences (hence, some matches were repeats); there were 13 false-positive matches and 12 false negatives; three partial matches were also made. With 99.47% precision and 99.51% recall, the diagnostic performance of this profile is near perfect.

Alongside this profile, PROSITE also contains a 17-residue pattern for the family, as seen in Table 3 (G_PROTEIN_RECEP_F1_1, PS00237). Against the same version of UniProtKB/Swiss-Prot, the pattern made 2142 matches in 2138 sequences: 153 of these were false positive; and 31 were partial matches. In addition, 454 sequences were noted as false negatives. Thus, with 92.86% precision and 81.42% recall, the pattern doesn't match the diagnostic performance of the profile. In general, where both patterns and profiles are used to describe a particular protein family or domain, the profile generally has the greater diagnostic power.

As profiles continued to outperform patterns, a growing profile library began to augment PROSITE: by August 2012, the number of profiles exceeded one thousand (Sigrist *et al.*, 2013); by August 2017, they comprised almost half the database. However, creating patterns and profiles, regularly assessing and refining their diagnostic behaviour in response to the changing size and composition of Swiss-Prot, and maintaining their annotation accordingly, is extremely labour intensive. Thus, while the philosophy of providing comprehensive manual annotation for every database entry adds significant value to the database, and still contributes to its popularity, the time-consuming nature of the task is one of the hardest challenges for curators, and has placed an inevitable brake on its growth. By August 2017, PROSITE provided descriptions of 1788 sites, domains and families, diagnosed by 2500 patterns and profiles.

PRINTS

The second pattern-recognition technique devised in response to the diagnostic limitations of some of the original PROSITE patterns was 'fingerprinting' (Attwood *et al.*, 1994). An early idea behind the development of PROSITE was that a pattern, defining a single conserved region, or motif, within a sequence alignment was sufficient to be able to diagnose a complete protein family. However, most alignments contain several motifs, often separated by regions that are poorly conserved and/or gapped. The concept of fingerprints thus stems from the observation that groups of motifs, and their unique inter-relationships, can together create distinctive signatures for particular protein families or domains. From a diagnostic perspective, this offers greater flexibility than patterns, as it affords the possibility to tolerate mis-matches at the level of individual motifs, without compromising the discriminating power of the fingerprint as a whole, as shown in Fig. 2.

The first fingerprint was created in an attempt to capture all known rhodopsin-like GPCRs in Swiss-Prot (Attwood and Findlay, 1993, 1994). The distinguishing trait of GPCRs is the presence of seven conserved transmembrane (TM) domains; the fingerprint therefore encoded each of these motifs. The resulting discriminator proved to be more robust than the existing PROSITE pattern for this family, which was originally based on a conserved region within TM domain 2 (see Table 3). This led the pattern to be

Fig. 2 Complete (human rhodopsin, OPSD_HUMAN) and partial (*C. elegans* putative GPCR, YMJC_CAEEL) matches with the rhodopsin-like GPCR fingerprint. The *C. elegans* protein has a clear relationship with this GPCR family, but lacks significant matches with the fourth and fifth TM domains.

revised (Attwood and Findlay, 1993, 1994), based instead on TM domain 3: this is more tightly conserved, and includes the G protein-interaction site at the N-terminal extremity of the second cytoplasmic loop; the revised pattern was also later complemented by a more potent profile.

In light of the success of the GPCR fingerprint, the technique was used to characterise a range of other protein families, several of which weren't yet available in PROSITE. The results were released in October 1991 in a new resource, initially known as the Features Database (Akrigg *et al.*, 1992). Inspired by PROSITE, the Features Database adhered to the underlying philosophy of adding value to its contents through hand-crafted annotation. Given their similarities, and their growing annotation burdens, there were obvious advantages to unifying their formats (Bairoch, 2000). Nevertheless, a proposal to the European Commission to unite their contents, to create the world's first integrated protein family resource, proved unsuccessful (Attwood *et al.*, 2011).

Despite this setback, both databases continued to evolve. The Features Database, which was growing at a steady rate of 200 fingerprints annually, was subsequently re-branded 'PRINTS' (Attwood and Beck, 1994; Attwood *et al.*, 1994). However, without a dedicated team of curators, this growth rate proved unsustainable. The last release of the PRINTS database was made available in 2012, with 2156 fingerprints encoding 12,444 motifs (Attwood *et al.*, 2012), and is still available for online searching.

Blocks

Following the development of PROSITE and PRINTS, similar attempts were made to characterise protein families, but avoiding heavy reliance on manual approaches to create the signatures and annotate their results. Amongst the first of these was a method that, like fingerprints, made use of multiple conserved motifs, or 'blocks', derived from sequence alignments (Henikoff and Henikoff, 1991). In this approach, the most conserved alignment regions were identified automatically using two independent motif-finding algorithms; only motifs identified by both algorithms were accepted in the final family-specific set of blocks, which were then deposited in the Blocks database.

Blocks' algorithmic approach meant that, for the same family of proteins, the identified blocks generally differed from motifs in the 'equivalent' fingerprint. Importantly also, the blocks-based approach didn't explicitly exploit the relationships between motifs, but treated each motif separately; the diagnostic behaviour of blocks and fingerprints designed to characterise the same families was therefore different. To afford users these different diagnostic perspectives, each release of Blocks was complemented with a copy of Blocks-format PRINTS, derived directly from the manually-selected motifs from the PRINTS database.

In the original versions of the Blocks database, blocks were derived from alignments of sequence families identified in PROSITE. However, as PROSITE's growth was curbed by its high level of manual processing, this was also limiting the growth of Blocks. By the late 1990s, information from a range of additional protein families had become available in complementary databases like PRINTS (Attwood and Beck, 1994), ProDom (Sonnhammer and Kahn, 1994), Pfam (Sonnhammer *et al.*, 1997) and DOMO (Gracy and Argos, 1998). A more comprehensive, non-redundant version of the Blocks database was therefore devised – termed Blocks+ – which included, in a stepwise fashion, i) all blocks derived from PROSITE, ii) blocks derived from PRINTS not present in PROSITE, iii) blocks derived from Pfam not present in PROSITE or PRINTS, and so on for ProDom and DOMO (Henikoff *et al.*, 1999). Eventually, this multiple-database pipeline was replaced by a more streamlined approach utilising protein families from the integrated database, InterPro (Apweiler *et al.*, 2001).

Even though Blocks releases were not reliant on manual annotation, database maintenance was still laborious, and production ceased in April 2007. The final release contained 29,068 blocks, representing 5900 sequence groups documented in InterPro 14.0. Although no longer maintained, Blocks and Blocks-format PRINTS are still available for searching online.

ProDom

A rather different analytical approach emerged from a study of protein modules. These are analogous to molecular building-blocks, discrete domains that have been combined in different ways during the course of evolution to create a range of multi-functional proteins. An automatic method was developed to recognise such modules and domains, and to cluster them into groups. The algorithm was applied to more than 21,000 full-length sequences in Swiss-Prot 21.0, and the resulting domain families were organised automatically into a database – this was ProDom (Sonnhammer and Kahn, 1994). Multiple alignments were also created for each group, from which consensus sequences were generated to facilitate database searches.

A particular challenge with this approach was that the clusters (and their alignments and consensus sequences) had to be recalculated for each release of Swiss-Prot. Not only was this onerous, but the resultant domain 'families' were not consistent between computations on successive Swiss-Prot releases. This lack of stability made indexing ProDom's contents problematic, and led to integration issues with early releases of InterPro (Apweiler *et al.*, 2001); moreover, as Swiss-Prot grew and TrEMBL (Bairoch and Apweiler, 1996) became part of the expanding target database (in 1996, TrEMBL 1.0 held ~105,000 sequences, almost twice the size of Swiss-Prot 34.0, with which it was released in parallel), this brought significant maintenance overheads. The last version of ProDom (ProDom 2012.1), based on more than 21 million full-length sequences from the December 2012 release of UniProtKB/Swiss-Prot and TrEMBL (UniProt Consortium, 2013), included more than 1.7 million domain families containing at least two sequences.

Pfam

During the decade following the release of the first 58 PROSITE patterns, protein family databases proliferated, and database maintenance issues began to take centre stage. The principal tension was between the need to provide users with high-quality, reliable information, and their desire for rapid access to the most comprehensive data. Databases like PROSITE and PRINTS focused on the former, using manual approaches to craft quality alignments and detailed annotation; resources like Blocks and ProDom, on the other hand, made concerted efforts to address the latter, as automation was the only practical way for databases to become more ‘complete’. A kind of hybrid approach was introduced with the advent of Pfam (Sonnhammer *et al.*, 1997), a Hidden Markov Model (HMM)-based database that included both annotated and automatically derived components (denoted Pfam A and Pfam B, respectively).

Conceptually, HMMs are similar to profiles, which model sequence alignments as strings of match, insert and delete states. The main difference is that, rather than using absolute scores, HMMs are probabilistic: i.e., match states instead contain amino acid probabilities within a given alignment column; and transition states denote transition probabilities to and from insert and delete states, reflecting the propensity to insert or skip a residue at a particular position. Pfam A (release 1.0) contained 175 of the most widely populated sequence clusters, seeded by family information from sources like PROSITE, ProDom, etc.; Pfam B contained 11,929 clusters, based on alignments constructed from the portion of Swiss-Prot not already represented in Pfam A (Sonnhammer *et al.*, 1997) – for Pfam 1.0, this was 81% of Swiss-Prot 33.0.

Although Pfam emerged almost ten years after PROSITE, the database nevertheless grew rapidly. In large part, this resulted from a shifting emphasis towards automation, as Pfam adapted to cope with the engorgement of TrEMBL (Finn *et al.*, 2016). Annotating the growing numbers of sequence clusters had become the most burdensome task; it was therefore decided to adopt the Wikipedia model, effectively outsourcing annotation to the community. This meant that, from release 25.0 onwards, the notes traditionally assigned to Pfam entries were to be largely replaced by Wikipedia articles. By March 2017, Pfam 29.0 contained 16,712 entries, and Pfam B, its automatically generated supplement, had been removed.

InterPro

The TrEMBL database, containing translations of all coding sequences in the EMBL data library (Emmert *et al.*, 1994), was released in 1996 as a computer-annotated supplement to Swiss-Prot (Bairoch and Apweiler, 1996). This provided rapid access to protein products of genomic data within a familiar Swiss-Prot-like framework, but in a relatively ‘raw’ state, with little annotation. In 1997, Bairoch, Attwood and Apweiler returned to the earlier discussion of the feasibility of uniting PROSITE and PRINTS. By then, however, the vision was more ambitious: the quest, to develop a resource to annotate TrEMBL entries, to add value to the deluge of uncharacterised genomic data pouring from sequencing projects, using signatures from several protein family resources, including ProDom and the newly announced Pfam database. This time, the case for integration was stronger, and the funding bid for the new project – termed InterPro – was successful. A beta release of InterPro was made in October 1999, characterising 2423 families and domains in Swiss-Prot 38.0 and TrEMBL 11.0: this ‘pilot’ release combined 1370 entries from PROSITE 16.0; 1157 fingerprints from PRINTS 23.1; 241 preliminary profiles from the Profile library; and 1465 entries from Pfam 4.0. It had thus taken seven years finally to realise the goal of an integrated protein family database (Apweiler *et al.*, 2001).

Although ProDom was part of the original InterPro proposal, it was nevertheless excluded from initial releases because the nature of its clusters fluctuated between different versions of Swiss-Prot. Before it could be meaningfully integrated, some means of assigning stable accession numbers to ProDom entries therefore had to be found. Another important factor

Table 4 Composition of InterPro release 64.0, July 2017

Partner database	Version	Entries	# Integrated	% Integrated
Pfam*	31.0	16,712	16,119	96
PANTHER*	11.1	91,538	6,224	7
TIGRFAMs*	15.0	4,488	4,448	99
PIRSF*	3.02	3,285	3,201	97
CDD	3.16	12,805	2,165	17
HAMAP	201.701.18	2,160	2,160	100
PRINTS	42.0	2,106	1,980	94
SUPERFAMILY*	1.75	2,019	1,479	73
ProDom	2006.1	1,894	1,308	69
PROSITE patterns	20.132	1,309	1,298	99
SMART*	7.1	1,312	1,264	96
CATH-Gene3D*	4.1.0	2,737	1,235	45
PROSITE profiles	20.132	1,174	1,142	97
SFLD*	2	480	146	30

Note: Asterisks denote partner databases that contribute HMM-based signatures to the resource.

tempered the early development of InterPro (and remains a challenge today): although conceptually straightforward, amalgamating the contents of PROSITE, PRINTS and Pfam was a major undertaking. The databases use different analysis methods to identify sequence groups; importantly, they also use very different terminologies to describe them - at the time, there was no common definition of what constituted a 'family', a 'superfamily', a 'domain family', and so on. Thus, trying sensibly to merge apparently equivalent database entries, whose terminologies and whose sets of identified sequences were different, was extremely difficult. To facilitate the integration process, initial work therefore focused on partner databases that offered some level of annotation. Hence, ProDom didn't appear in InterPro until release 1.2 in June 2000, to which it contributed 540 entries.

During the next decade, additional resources were considered as potential InterPro partners (Blocks was amongst these; however, by 2001 it was taking source data directly from InterPro, so its inclusion in InterPro would have added a kind of circularity), resulting in seven more databases joining the InterPro consortium (Hunter *et al.*, 2009). By 2017, with 14

Protein family membership

- F** G protein-coupled receptor, rhodopsin-like (IPR000276)
- F** Opsin (IPR001760)

Domains and repeats

Detailed signature matches

Fig. 3 Output from a search of InterPro with the sequence of rhodopsin from the Japanese flying squid (P31356, OPSPD_TODPA). Matches to signatures within each partner database are colour-coded: PROSITE (patterns), yellow, (profiles) orange; PRINTS, green; Pfam, blue; PANTHER, brown; Gene3D, purple; SUPERFAMILY, black. The 'anatomy' of the sequence is revealed in terms of the overarching superfamily and specific family to which it belongs, the functional sites (G protein-coupling, retinal-binding) and C-terminal repeats it contains, the location of its 7TM-domain and the positions of its constituent TM regions.

contributing data sources, the annotation challenges had become immense, and now lend InterPro a level a complexity that was inconceivable 25 years ago, when integrating protein family databases was first discussed. [Table 4](#) gives a hint of this complexity: in it are listed the versions of the partner databases contributing to the July 2017 release, their sizes and the numbers of their entries included in the resource.

While most of the contents of each partner database are incorporated, aberrant signatures (i.e., those that match unrelated sequences outside their intended scope), or differences in and between them, cause integration of some entries to be deferred. Other concerns include i) how to reconcile sequence-based families with structure-based families (e.g., such as defined in CATH-Gene3D ([Dawson et al., 2017](#)) and SUPERFAMILY ([Oates et al., 2015](#))), whose conceptual models of protein families differ considerably; and ii) how to manage and compare the contents of partner databases that contain vast amounts of (largely automatically generated) data relative to others (e.g., PANTHER ([Mi et al., 2017](#))), especially in cases where their signature collections change substantially from release to release.

The data complexity and semantic issues outlined above make efficient processing very difficult, and annotating the results a continual headache. In consequence, note the discrepancies between columns 3 and 4 of [Table 4](#) – while the integration level of the contents of some partner databases is 90% or more, for others it is less than 50%. Notwithstanding the challenges, with 30,876 entries in release 64.0, InterPro is the largest integrated protein family database, offering the most comprehensive opportunity for protein family characterisation in the world ([Finn et al., 2017](#)). Helping to fulfil its original rationale, more than 80% of TrEMBL entries can now achieve at least some level of annotation using the resource.

InterPro's considerable diagnostic power, with its multiple-database perspective, is illustrated in [Fig. 3](#), which shows the result of searching the database with the sequence of rhodopsin from the Japanese flying squid. The sequence is diagnosed as belonging to the rhodopsin-like GPCR superfamily, being specifically a member of the opsin family; it contains a G protein-coupling motif in TM region 3, and a retinal-binding site in TM region 7; the location of its 7TM-domain is identified, as are the positions of each of the constituent TM regions; and a repetitive region is confirmed to reside C-terminally to the 7TM-domain. No other single database can dissect, in such an extensive, fine-grained way, the 'anatomy' of a protein sequence.

As InterPro has evolved, its composition has changed markedly. Early releases provided a powerful balance of the diagnostic opportunities afforded by patterns, profiles, fingerprints and HMMs, yielding a resource whose diagnostic power was greater than the sum of its parts. Over the years, this balance has, to a large extent, been diluted as more HMM-based databases joined the consortium. [Table 4](#) reveals that the bulk of the contributions to InterPro are now HMM-based (Pfam, PANTHER, TIGRFAMs, PIRSF, etc.); a significant challenge for maintaining InterPro's health in future will therefore be to retain the broad scope and resilience of its original diagnostic diversity. Perhaps a more pressing and invidious threat concerns the financial viability of InterPro's partner resources. As mentioned earlier, several family databases have struggled to sustain regular release schedules; some have ceased production. Many of these resources began effectively as cottage industries, the 'pet' projects of enthusiastic individuals, shared publicly for the benefit of the community. However, without adequate funds, databases cannot survive. It is particularly ironic, then, that the value and importance of InterPro was recently recognised when it was designated an ELIXIR 'core resource'. InterPro's uniqueness derives from the contributions of its partner databases, yet many of these are neither part of ELIXIR, nor considered sufficiently financially viable to be eligible as core resources, presenting a kind of conundrum for InterPro's continuity (and a problem for its future diagnostic finesse).

Closing Remarks

Protein family databases have come a long way since Doolittle's suggestion, more than three decades ago, that sequence patterns could characterise the potential functions of unannotated sequences, and Bairoch created the first protein family database based on such patterns. Today, there are numerous publicly available databases that offer insights into protein functions, structures and family relationships, many more than have been integrated into InterPro. Nevertheless, InterPro stands apart, a union of many different partners, whose different philosophical and methodological approaches have been melded into a uniquely powerful whole, one that now provides the backbone of annotation for newly determined sequences entering TrEMBL, and one that continues to provide a versatile, high-quality diagnostic tool for researchers around the world.

Acknowledgment

We are extremely grateful to Amos Bairoch for the time he devoted to excavating his personal archives, retrieving 'ancient' pre-Web files and emails to verify and augment some of the PROSITE-related information presented here.

Biographical Sketch

Terri is professor of Bioinformatics at the University of Manchester. Her interests in protein sequence analysis led to the creation of various databases (e.g., PRINTS, InterPro) and software tools like Utopia Documents, which uses semantic technologies to integrate research data with scientific articles. She has written several bioinformatics textbooks and reference works. She currently Chairs the GOBLET Foundation, and leads the development of ELIXIR's Training e-Support System, TeSS.

Alex is coordinator for the InterPro and EMBL-EBI Metagenomics databases at the European Bioinformatics Institute. He obtained his DPhil in pharmacology from the University of Oxford, and was previously employed as a molecular biologist at the Institute of Psychiatry in London, before moving to the University of Manchester to work on protein family databases. He joined EMBL-EBI in 2011.

Introduction

A fraction ranging from 20% to 30% of all genes in any organism encodes for transmembrane (TM) proteins (Krogh *et al.*, 2001). This class is involved in a wide range of functions, enabling almost all communications of matter, energy and information across the biological membranes enclosing cells and organelles. Indeed, only hydrophobic and small molecules can diffuse through membranes and cross them without need of proteins. Owing to their crucial role in physiological processes, TM proteins are the privileged target of drugs: in humans, TM proteins represent around 50% of known pharmaceutical targets (Bakheet and Doig, 2009).

TM proteins consist of three regions: the TM region spans the hydrophobic phase of the lipid bilayer and separate two domains (called intra-cellular and extra-cellular domains, in the case of proteins inserted in the plasma membrane) that are in contact with the aqueous solvent. In multi-pass TM proteins (having more than one membrane-spanning segment), the three regions comprise discontinuous protein segments that fold to form structural domains responsible of protein functions and interaction with other proteins and molecules. Specifically, TM domains can serve, for example, as anchors, channels (gated or not, nonspecific or selective), signal transducers, modifiers of physical and chemical properties of the membrane.

Two major structural classes of transmembrane proteins have been discriminated so far: all- α and β -barrel, whose membrane-spanning segments are α -helices or β -strands, respectively (Fig. 1). Indeed, to stabilize the interaction between the protein and the membrane, the membrane-spanning segments adopt a regular secondary structure: this allows to avoid contacts among the polar groups of the backbone and the hydrophobic chains of the lipid bilayer.

All- α TM proteins known to date comprise a number of helices ranging from 1 to 24 (as in the case of the voltage-gated sodium channel NavPaS from *Periplaneta americana*, PDB code: 5X0M) and have been found in all membrane types with the exception of the outer membrane of Gram-negative bacteria where only β -barrel TM proteins are present. TM β -barrel domains result from the interaction of different β -strands, ranging from 8 to 60 (as in the case of Type II secretion system GspD from *Escherichia coli*, PDB code: 5WQ7) and often including different protein chains. β -barrel TM proteins are also present together with all- α TM proteins in the outer membrane of mitochondria and chloroplasts.

The crystallization of TM proteins and the possibility to resolve their structure by means of X-ray diffractometry is hampered by the need of mimicking with detergents the tripartite bi-phasic environment where TM proteins are stable. Recently, improvements of cryo-electron microscopy technique, not requiring crystallization, opened a new way to resolve the structure of TM protein (Fernandez-Leiro and Scheres, 2016). However, experimental characterization of TM protein structure is still challenging. Computational methods are required for formulating reliable and testable hypotheses on conformation and functional role of TM proteins, whose covalent structure can be deduced from the translation of genomes sequenced with modern Next Generation Sequencing technologies at ever increasing throughput and decreasing cost.

The major computational problems related to TM domains are:

Fig. 1 Two structural classes of TM proteins.

Table 1 TM proteins in UniProtKB (Dec 2017)

Keyword	UniProtKB	With structure	SwissProt	With structure

Transmembrane α -helix	20,079,319	4,496	76,687	2,990
Transmembrane β -strand	74,199	115	1,027	95

- The determination of the number of membrane-spanning segments and their position along the sequence.
- The determination of the orientation of the membrane protein with respect to the lipid bilayer (topology).
- The determination of the three-dimensional arrangement of the TM spanning segments.
- The determination of the function of TM proteins, including their subcellular localization.

Databases

UniProtKB

Table 1 shows the status of the 2017_12 release of UniProtKB ([The UniProt Consortium, 2017](#)): it contains 20,227,696 proteins labelled with the keyword “transmembrane” (KW-0812), out of 102,804,649 total sequences (19.7%). When restricting to the subset containing the manually curated entries of SwissProt, TM proteins represent 78,045 sequences out of 556,388 (14.0%). Only a 3112 SwissProt sequences (corresponding to 4.0%) are endowed with a three-dimensional structure, at least for one domain. The fraction is much lower when considering all UniProt (0.02%). Moreover, in most cases the experimentally resolved structure is partial and does not include the TM domain. For that reason, specialized datasets collecting proteins with structurally resolved TM domain are needed (see next section).

With few exceptions, TM proteins in UniProtKB are also marked with two more labels, identifying the type: “transmembrane helix” (KW-1133) and “transmembrane beta strand” (KW-1134). It is evident, from the figures in **Table 1**, that most of the known TM proteins belong to the all- α class.

Databases of Structurally Resolved TM Domains

The oldest collection of TM domains with well resolved structure is maintained at UC Irvine laboratory of Prof. White (see “Relevant Websites section”) and, when excluding monotopic proteins not spanning the membrane, it counts 2372 coordinate files relative to 735 unique proteins (release: Jan 2018). The resource collects and expertly classifies the information deposited at the PDB about the available TM domain structures.

One major problem in the analysis of TM protein structure is that neither the exact position of the phospholipids nor the orientation of the protein with respect to the membrane plane are known. Different procedures have been implemented to infer the interaction between membranes and TM proteins, analyzing the physical-chemical properties of the protein surface as determined from the crystallographic structure. Some of them are listed below.

- PDBTM (see “Relevant Websites section”, [Kozma et al., 2013](#)) uses a geometrical approach to locate the most likely position of the lipid bilayer: accessible surfaces of hydrophobic (F, G, I, L, M, V, W and Y) and hydrophilic residues (A, C, D, E, H, K, N, P, Q, R, S and T) are computed; the membrane, represented as two parallel planes more than 15 Å apart, is positioned to minimize the exposure of hydrophobic residues with some constraint on the protein backbone geometry. PDBTM (release: Jun 2017) contains data from 3227 PDB chains, 2848 all- α and 366 β -barrel.
- OPM (Orientations of Proteins in Membranes, see “Relevant Websites section”, [Lomize et al., 2006](#)) adopts an energy based approach in which each protein is modeled as a rigid body with flexible side chains, while the bilayer is represented as a planar hydrophobic slab of adjustable thickness ranging between 21.1 Å and 43.8 Å, depending on the type of biological membrane; transfer energy is calculated at an all-atom level using atomic solvation parameters determined for the water-decadiene system, neglecting explicit electrostatic interactions and contributions of pore facing atoms; most probable protein arrangement is computed by minimizing its transfer energy from water to the membrane. OPM contains (Dec 2017) data from 1783 non-redundant PDB files, 1554 all- α and 229 β -barrel.
- MemProtMD (see “Relevant Websites section”, [Stansfeld et al., 2015](#)) performs a coarse-grained molecular dynamics simulation: groups of atoms are treated collectively as large particles, allowing to increase timescales and system dimensions; the dynamics of the system comprising protein, membrane lipids and solvent is simulated for 1 μ s and the self-assembly of the system is followed. Different lipid species are used in different simulations. MemProtMD currently contains simulations for some 3000 proteins.

Computational Prediction of TM Segments and Topology

Computational characterization of TM protein sequences routinely starts with the prediction of the number of TM segments, of their location along the sequence and their orientation with respect to the lipid bilayer.

Different methods implement different strategies for detecting signals embodied in the sequence in relation to the interaction with the membrane phospholipids and the internal and external polar environments. Local sequence composition is the major source of signal, often complemented with the evolutionary information obtained from multiple sequence alignment of similar proteins. Depending on the TM protein type, the prediction must satisfy different constraints on the number of membrane-spanning segments and their length. In all- α TM proteins the number of membrane-spanning elements is not lower-bounded and their length ranges from 16 to more than 40 residues, depending on their tilt with respect to the membrane plane. Most helices have a clear hydrophobic character, but helices surrounding a pore or in reciprocal interaction routinely show a weaker hydrophobic signal and exhibit a more amphipathic quality. An important topogenic signal is the so-called “positive inside rule” stating that, owing to the unbalance of charge density between the two sides of plasma membranes, the loops facing the cytoplasmic phase (inner loops) are richer in positively charged residues than loops facing the extra-cellular environment (outer loops) (von Heijne, 1989). In eukaryotes, the rule can be applied also to proteins inserted in other membranes, but the definition of inner and outer loops must be redefined for each membrane type (Sharpe *et al.*, 2010).

The generation of the circular arrangement of β -barrels requires at least 8 segments and, so far, the largest resolved barrel consists of 60 strands. In some cases (e.g., TolC, α -hemolysin, Type II secretion system GspD), the functional protein is a multimeric complex in which strands from different subunits interact to form the complete barrel. The minimum number of strands per chain is equal to two. The minimum length of each strand is 6 residues, needed to span the membrane width with an extended conformation. The longest TM β -strand crystallized so far is 24 residue long. Since β -barrels usually delimitate water-filled pores, the strands consist of alternating hydrophobic and hydrophilic residues. Statistical analysis on available structures also reveals that in Gram-negative bacteria, loops exposed towards the extracellular space (outer loops) are, on average, longer than loops facing the periplasmic space (inner loops) (Martelli *et al.*, 2002).

Several confounding factors complicate the prediction of the correct topology. In particular, in the case of all- α membrane proteins the presence of a N-terminal signal peptide with a clear hydrophobic character can lead to the misprediction of an extra helix. Moreover, some all- α TM protein contain partially reentrant segments that span only a portion of the bilayer and strongly challenge the computational characterization of TM segments (Tsirigos *et al.*, 2018).

Scale-Based Methods

Early methods for the localization of TM segments, in particular α -helices, rely on the search of hydrophobic segments along the sequence. More than 20 different scales endowing each residue type with a hydrophobicity value have been proposed to this aim (see “Relevant Websites section”). Among them, the most adopted is the Kyte-Doolittle hydropathy scale (Kyte and Doolittle, 1982) that combines data on water-vapor transfer free energies of the different residues and their exposure distribution in a set of structurally resolved proteins.

Thermodynamic scales have been also generated on the basis of the free energy of transfer between water and hydrophobic liquid (octanol) and between water and phosphocholine interface (White and Wimley, 1999). More recently, a “biological” hydrophobicity scale has been compiled starting from the measurement of the propensity of each residue to be translocated in the endoplasmic reticulum membrane by translocon protein Sec61 (Hessa *et al.*, 2005). This scale has been proved to outperform the others because it probably better casts the physical-chemical constraints deriving from both the protein-membrane interaction and the insertion process. It has been implemented in the SCAMPI2 predictor (Peters *et al.*, 2016).

Hydrophobicity scales are routinely applied to the recognition of TM α -helices by averaging over a window and by searching for hydrophobic stretches at least 15 residue long. The presence of weakly hydrophobic or amphipathic helices strongly limits the performance of scale-based methods. An evolution of the scale-based approach is the first version of MEMSAT (Jones *et al.*, 1994) where 5 different scales (Helix inner end, Helix middle, Helix outer end, Inner loop, Outer loop) are derived from the analysis of 83 all- α TM proteins. During the prediction phase, the five signals computed along the sequence are integrated with a dynamic programming procedure casting the basic grammatical constraints of the topology of all- α TM proteins. Scale-based methods are of scarce relevance for the prediction of β -barrel membrane proteins.

Machine-Learning Based Methods

The best performing methods for the topology prediction of both all- α and β -barrel TM proteins are based on machine-learning approaches such as Neural Networks (NN), Support Vector Machines (SVM), Hidden Markov Models (HMM) and Conditional Random Fields (CRF). Machine learning methods require the availability of a possibly large dataset of proteins with known topology that is used to fix the trainable parameters of the different methods. If the training set is large and diverse enough, the training procedure allows to extract the general rules of the mapping between the sequence and the topology. After the training phase, the parameters can be applied to the prediction of uncharacterized protein sequences. The performance assessment of machine-learning based methods requires a careful validation on protein sets completely independent of the training set. The adoption of machine learning tools allows to analyze more complex input encoding than the simple sequence. In particular, it has been proved that the introduction of evolutionary information extracted from multiple sequence alignments of similar proteins and encoded with sequence profiles largely improves the prediction performance. This has been proved for the prediction of both all- α and β -barrel TM proteins using NNs (Rost *et al.*, 1995; Jacoboni *et al.*, 2001) and HMMs (Martelli *et al.*, 2002; Martelli *et al.*, 2003). While NNs and

SVMs are very efficient in analyzing the local context of a residue, graphical models such as HMMs and Grammatical Restrained Hidden CRFs cast in a more natural way the grammatical constraints that TM proteins must satisfy (schematically depicted in Fig. 2). The complementarity among methods makes it possible to improve the predictive performance by adopting ensemble methods (Martelli *et al.*, 2003; Bernsel *et al.*, 2009) or hybrid approaches (Savojardo *et al.*, 2013).

Table 2 lists some of the most adopted methods for the prediction of all- α TM proteins, specifying whether they are able to deal with reentrant regions (RR column) and with the possible presence of N-terminal signal peptides (SP columns).

Table 3 lists some of the most popular methods for the prediction of β -barrel TM proteins.

Three-Dimensional Reconstruction

The prediction of the TM protein topology is of great help for classifying new protein sequences, restricting the set of possible conformations they can assume and functions they can perform. In some cases, prediction of protein topology improves the search of a structural template in the PDB and assists the target-template alignment for comparative modelling, even at low sequence identity. However, due to the scarcity of structural information on TM proteins, methods allowing the template-independent reconstruction of the 3D structure of TM domains are needed. In most cases, these methods start from a topology prediction and predict the most probable contacts among TM-segments. On this basis, optimization procedures can be applied to search for the most favorable arrangement of the TM segments inside the lipid bilayer, after defining a score accounting for inter-segment and segment-membrane interactions.

Available methods for contact predictions in all- α proteins include:

- MEMPACK (see “Relevant Websites section”, [Nugent and Jones, 2010](#)), a method to predict lipid exposure, residue-residue contacts, helix-helix interactions and ultimately overall protein helical packing. Individual classifiers for lipid exposure and residue contacts are based on SVMs and have been trained on data derived from the OPM and PDBTM as well as molecular dynamics data extracted from the Coarse Grained Database ([Chetwynd et al., 2008](#)) (for lipid exposure prediction).
- TMHcon (see “Relevant Websites section”, [Fuchs et al., 2009](#)), a method for predicting helix-helix contact in TM proteins based on NNs and different input features, including: evolutionary information, sequence distance and co-evolution measures of residue pairs as well as protein global features such as protein length and number of TM segments.
- FILM3 (see “Relevant Websites section”, [Nugent and Jones, 2013](#)), a method combining PSICOV ([Jones et al., 2012](#)), an advanced residue-residue contact predictor, with TM topology prediction (performed using MEMSAT-SVM) and fragment selection and assembly. The main novelty of FILM3 consists in the adoption of scoring energy functions (used for fragment selection and assembly) entirely based on distance constraint imposed by predicted TM segments and contacts predicted by PSICOV.
- MemBrain (see “Relevant Websites section”, [Yang and Shen, 2018](#)), a recent approach to predict inter-helix contacts based on deep learning methods.

Functional Characterization

Structural characterization of TM proteins helps in formulating hypotheses about their role in the complexity of biological functions. However, the three-dimensional reconstruction is not always feasible and, in some cases, similar structures are associated to different specific functions or subcellular localizations. For this reason, methods for inferring protein function and localization from sequence have been implemented.

To date, the only prediction method for protein localization specific for TM proteins is MemLoc ([Pierleoni et al., 2011a](#); see “Relevant Websites section”) that classifies protein sequences into three subcellular localizations (Plasma membrane, Organelle membranes, Internal membranes) with a SVM. The MemPype system ([Pierleoni et al., 2011b](#); see “Relevant Websites section”) integrates MemLoc with similarity-based inference methods and tools for the prediction of topology, presence of signal peptide and GPI-anchor.

General-purpose systems for inferring protein functions can be applied to TM proteins (see also [Martelli et al., 2017](#)). The basic idea of these methods is to extrapolate functional information present in databases in order to annotate sequences lacking experimental characterization. For example, the Bologna Annotation Resource (BAR3.0, see “Relevant Websites section”) is a prediction tool that exploits large-scale clustering of UniProtKB sequences resulting from the application of strict similarity constraints (more than 40% sequence identity on an alignment coverage larger than 90%; [Profitti et al., 2017](#)). Functional characterization of each cluster is derived from proteins carrying functional annotation (in terms of Gene Ontology, GO) in UniProtKB, after an analysis of statistical significance. This procedure allows to spread functional annotation to all the members of the clusters. For example, in the present version, BAR 3.0 contains 2294 protein sequences experimentally associated with the GO term “integral component of membrane” (GO:0016021) or its descendants, and the BAR3.0 structure allows spreading the annotation to 751,272 protein sequences.

Prediction of Protein Localization

Kenta Nakai, The University of Tokyo, Tokyo, Japan

Kenichiro Imai, Advanced Industrial Science and Technology, Tokyo, Japan

Introduction

In the body of multicellular organisms, there are many cell types, each of which contains a set of proteins, some of which are specific to it while some are ubiquitous to all cell types. With the development of single-cell transcriptomics technology, precise mapping of each protein to its expressed cells is ongoing. Such information will be undoubtedly useful in clarifying the cellular function of these proteins. Similarly, each protein is localized at a compartment(s) (organelle) within a cell (or excreted to outside of the cell). Such knowledge would be also useful in understanding the function of the protein because each compartment plays some specific roles within the cell. Especially, knowledge on whether a protein is secreted or not may have particular importance in pharmaceutical and medical sciences. And it should be noted that the information of protein subcellular localization is also important for unicellular organisms, such as bacteria. Attempts to systematically determine the subcellular localization within a cell have been performed in the field of proteomics. Nowadays, even the information of semi-quantitative localization frequency at multiple localization sites for a protein is accumulating.

It has been demonstrated that many (if not all) proteins are sorted to their final localization site after their synthesis in the cytosol according to the information that is encoded as part(s) of their own amino acid sequence (known as the signal hypothesis). Typically, such information is encoded as an N-terminal presequence and is called the targeting signal. In other words, some subcellular machinery recognizes and interprets such signals in the nascent proteins. Therefore, the prediction of protein subcellular localization from their amino acid sequence can have some extra biological rationale: If we can mimic the recognition process within the cell, we would be able to predict the localization, in principle. For practical purposes, however, additional information, such as the protein–protein interaction data, could be used. It should be also emphasized that the prediction problem has been used as a test bed for a variety of machine-learning algorithms probably because of its simplicity in scheme and its potential practical value. In this article, we will sketch a brief overview of this field, introducing some representative works. Finally, we will discuss its future directions.

Topics

Prediction of Subcellular Localization Sites

Basic prediction scheme

Since possible repertory of localization sites can be different between organisms, the basic input information is a set of a (precursor) amino acid sequence and its species origin. In eukaryotic cells, the category has been conventionally divided into animal cells and plant ones; unicellular eukaryotes, such as yeasts, can be treated as an animal or a special type of plant lacking chloroplasts. In many cases, the repertory for animal cells are: The cytosol, the nucleus, the mitochondrion, the endoplasmic reticulum (ER), the Golgi apparatus, the lysosome, the plasma membrane and the extracellular space (i.e., excreted). In plants, vacuoles are usually treated as equivalent with lysosomes in animals. In addition, plastids (typically chloroplasts) are added in plants. Sometimes, (integral) membrane proteins in compartments, such as mitochondria, are collectively treated as membrane proteins. It is known that some of the above compartments, such as mitochondria and plastids, have further precise structures because they are composed of multiple membranes. The nucleolus in the nucleus would be regarded as an independent site. However, attempts to include more precise predictions are rare mainly because of the difficulty in their data size: If a site contains only a small number of known proteins, its treatment in the machine-learning scheme is difficult. Similarly, in spite of their biological importance, peroxisomes are often not included in the repertory because of their relatively small sample size. Sometimes, cytoskeletal proteins are regarded as an independent site. The treatment of peripheral membrane proteins, that is, proteins that are weakly bound to the membrane mainly through protein–protein interaction, is quite difficult (except the cases when they are the lipid-anchored proteins). Theoretically, they can be treated as soluble proteins but both experimental data and practical expectation prefer them to be treated as membrane proteins. In bacterial predictions, the repertories have been classified into two, depending on the presence or the absence of the outer membrane: Gram-negative and Gram-positive bacteria. In Gram-positive bacteria, the repertory is the cytoplasm, the cell membrane, and the extracellular space while in Gram-negative ones, it is the cytoplasm, the inner membrane, the periplasm, the outer membrane, and the extracellular space. The cell membrane in Gram-positive bacteria is considered to be equivalent with the inner membrane in Gram-negative bacteria. Detailed attempts to predict archaeobacterial proteins are few and they seem to have been practically treated as a kind of Gram-positive bacterial protein.

Since the N-terminal part of a protein can affect its localization significantly, the input amino acid sequence must be the accurate precursor sequence. However, it is often the case that the translation site of a protein is not experimentally determined. Moreover, it is known that the translation site can be switched in various conditions because of alternative choices of

transcriptional start sites and/or alternative splicing. Thus, predicting the potential changes of localization sites depending on the choices of translational start sites would be a future direction in this field (see the concluding remarks).

In many cases, the most probable localization site or a list of possible sites with p values are provided in the prediction. Recently, there have also been many attempts to extend the scheme to treat with proteins that are localized at multiple sites. However, objective evaluation of their performances is difficult because both systematic and quantitative data of multiple localization have been quite rare, if any.

Conventionally, the prediction accuracy of a prediction method is assessed using the n -fold cross validation test, including the jack-knife test, where the number of testing data is one. As for the measure of prediction performance, standard measures in machine learning, such as the overall accuracy, the sensitivity/specificity (or precision/recall), and the Matthew's correlation coefficient are often used.

General prediction methods

Many prediction methods of subcellular localization sites have been developed and improved by combining biological or empirical sequence features correlated with subcellular localization with a variety of machine-learning algorithms, such as the k -nearest neighbor classifier, the support vector machine, and deep learning: PSORT (Nakai and Kanehisa, 1992), CELLO 2.5 (Yu *et al.*, 2006), WoLF PSORT (Horton *et al.*, 2007), MultiLoc2 (Blum *et al.*, 2009), SherLoc2 (Briesemeister *et al.*, 2009), YLoc (Briesemeister *et al.*, 2010), iLoc-Euk (Chou *et al.*, 2011), Loctree3 (Goldberg *et al.*, 2014), and DeepLoc (Almagro Armenteros *et al.*, 2017).

Prediction features generally used in the prediction of subcellular localization sites are roughly categorized into three types: Targeting signal features, sequence features, and annotation-based features. The information of targeting signals gives powerful prediction features and thus is detailed in the next section. The targeting signals are roughly classified into two classes: N-terminal targeting signals and non-N-terminal targeting signals. Representative N-terminal targeting signals are the signal sequence for the secretory pathway, the chloroplastic targeting signal, and the mitochondrial targeting signal. Whereas, the nuclear localization signal (NLS) and the nuclear export signal (NES) are usually located in the internal position of protein sequences, and peroxisomal targeting signal 1 (PTS1) is located at the C-terminus of proteins.

Sequence features are heavily used in localization prediction since some differences in the sequence features are empirically known to be correlated with different localization sites. Note that these sequence features may not be directly related to protein targeting itself. Representative sequence features are a series of expanded amino acid compositions of the entire sequence, such as the content of dipeptides, n -grams, k -mers, and the pseudo amino acid composition. Pseudo amino acid composition is reported to be more informative in terms of incorporating sequence-order information of a protein sequence (Chou, 2001). Functional motifs are also used in the prediction because some sequence motifs are directly related to the targeting signals and some functional information is closely related to the function of a localization site (e.g., the DNA-binding motif).

Typical annotation-based features are experimentally verified localization information found in UniProt or GO terms, in addition to the information of functional domains, protein-protein interaction and the text information from PubMed abstracts. Those annotation-based features are transferred from homologous proteins or the protein itself. In those features, the transfer of localization annotation from homologous proteins seems to be practically useful. Indeed, a simple homology-based inference outperforms methods based on machine learnings (Imai and Nakai, 2010) if a homologous protein with localization annotation is available.

Evaluation of prediction performance is a difficult issue in subcellular localization prediction. There is often some overlap between the training and the test sets of different methods since most methods use UniProt annotation for making these datasets. To evaluate the prediction performance with less bias, Salvatore *et al.* (2017) recently made a benchmark dataset from new data obtained by recent large-scale experimental studies in human cells and examined the performance of six state-of-the-art methods (CELLO 2.5, LocTree2, MultiLoc2, SherLoc2, WoLF PSORT and YLoc) (Salvatore *et al.*, 2017). In this assessment, CELLO 2.5, SherLoc2, LocTree2, and YLoc showed better performance (F_1 score=0.70), where F_1 score=2((precision $\times$ recall)/(precision + recall)). Also they developed an ensemble method, SubCons that combines four predictors (CELLO2.5, LocTree2, MultiLoc2 and SherLoc2) using a Random Forest classifier and it outperformed the six methods (F_1 score=0.79).

Targeting Signal Prediction

Prediction of signal sequence

Signal sequences (signal peptides) are the N-terminal sorting signal that targets the linked protein to the secretory pathway in eukaryotes and prokaryotes. About 10%–20% of eukaryotic proteome and 10% of bacterial proteome have been estimated to have the signal sequence (Kanapin *et al.*, 2003; Ivankov *et al.*, 2013). In eukaryotic cells, the signal recognition particle (SRP) cotranslationally recognizes the signal sequence upon its emergence from the ribosome and transfers it to the Sec61 translocon in the ER membrane (Nilsson *et al.*, 2015) via the SRP receptor. In bacterial cells, the SRP pathway is mainly used for targeting the membrane proteins with noncleaved signal sequence (signal anchors). Instead, secretory proteins containing the signal sequence are recognized by SecA, which drives the translocation through the SecYEG translocon (Kudva *et al.*, 2013). The signal peptidase cleaves signal sequences and the mature proteins are generated. Signal sequences do not share sequence similarity but share some characteristic features (von Heijne, 1990): Signal sequences are on average 16–30 amino acid residues in length and

comprise characteristic tripartite architecture: A positively charged *n*-region, a central hydrophobic *h*-region and a *c*-region with the cleavage site for signal peptidases. The cleavage site has a consensus pattern known as the -1,-3 rule: Amino acids with small side chains are preferred at the -1 position of signal sequences and no charged amino acid residues are preferred at their -3 position.

For predicting the signal sequence and its cleavage site, many prediction methods, such as SignalP (Bendtsen *et al.*, 2004; Petersen *et al.*, 2011), Signal-CF (Chou and Shen, 2007), and Signal-BLAST (Frank and Sippl, 2008), have been developed with the characteristic features. According to an assessment study in 2009 (Choo *et al.*, 2009), SignalP 3.0 achieves the best overall accuracy (0.872–0.914) in eukaryotic, Gram-positive, and Gram-negative bacterial data sets. Therefore, the discrimination between secretory and nonsecretory proteins (not including membrane proteins) based on the signal sequence prediction is the most successful in targeting signal predictions. However, those methods share a problem: Difficulty in the discrimination between the signal sequence and the transmembrane region. This problem will yield many false-positive predictions from N-terminal transmembrane regions when the methods are applied in proteomic analyses. Recently, SignalP (SignalP 4.0) was updated to tackle the problem using two types of neural network-based methods, SignalP-TM and SignalP-noTM: SignalP-TM has been trained with sequences containing transmembrane segments in the dataset while SignalP-noTM has been trained without those sequences (Petersen *et al.*, 2011). SignalP 4.0 shows better discrimination between signal peptides and transmembrane regions, and consequently achieves the best signal sequence prediction. On the other hand, there is still room for improvement on the cleavage site prediction: Precision and sensitivity of current methods hovers around ~66% and ~68%, respectively.

Prediction of mitochondrial targeting signal

Mitochondria have been estimated to host 1000–1500 distinct proteins, respectively (Meisinger *et al.*, 2008). The vast majority of mitochondrial proteins are encoded in the nuclear genome and imported by the translocases in the mitochondrial outer and inner membranes. About a half of mitochondrial proteins possess an N-terminal cleavable targeting signal (presequence), while the remaining proteins are thought to have a noncleavable internal targeting signal (Chacinska *et al.*, 2009). The mechanism of presequence-dependent targeting and the features of the presequence are well studied, however, the targeting mechanism with the internal targeting signal is still unclear. Thus, the main target of mitochondrial targeting signal prediction has been based on the presequences. Presequences-containing proteins are translocated by the outer and the inner membrane translocase, TOM and TIM23-PAM complexes (Schulz *et al.*, 2015; Wiedemann and Pfanner, 2017). Presequences have a length of 20–60 amino acid residues (Calvo *et al.*, 2017) and do not share sequence similarity. However, they exhibit a few characteristic features: A high composition of arginine and near absence of negatively charged residues (von Heijne, 1986; Schneider *et al.*, 1998). They are also often capable of forming a local amphiphilic α -helical structure with hydrophobic residues on one face and positively charged residues on the opposite face (Chacinska *et al.*, 2009; Fukasawa *et al.*, 2015). The presequence is cleaved in the matrix by the mitochondrial processing peptidase (MPP) and some of them are subsequently further cleaved by the intermediate peptidases, such as Oct1 and Icp55 (Mossmann *et al.*, 2012). The cleavage by MPP occurs at a position that is two amino acids C-terminal from an arginine (the R-2 motif). Icp55 and Oct1 subsequently cleave one amino acid and eight amino acids, respectively. Therefore, proteins cleaved by MPP + Icp55 have an arginine at position -3 (the R-3 motif) in the presequence while proteins cleaved by MPP + Oct1 have an arginine at position -10 (the R-10 motif).

Widely used presequence prediction methods, such as MitoProtII (Claros, 1995), TargetP (Emanuelsson *et al.*, 2000), Predotar (Small *et al.*, 2004), and MitoFates (Fukasawa *et al.*, 2015) were developed using machine-learning techniques with these properties of the presequences. These tools are also capable of predicting the presequence with its cleavage site. MitoProtII and MitoFates are specific predictors for the (mitochondrial) presequence, while TargetP and Predotar integrate other N-terminal targeting signal predictions, such as the secretory signal sequence and the chloroplastic targeting signal. Among those tools, Mitofates performs better in predicting both the presequence existence and the cleavage site: Precision and recall of 0.79 and 0.80 in the presequence prediction and the sensitivity of cleavage site detection is 71% (Fukasawa *et al.*, 2015). However, proteomic analyses of N-termini of mitochondrial proteins of mouse and yeast point out low accuracy (especially in the cleavage site prediction) of those presequence prediction tools (Vögtle *et al.*, 2009; Calvo *et al.*, 2017). A cluster analysis of yeast presequence data obtained from the proteomic analysis with features used in the presequence prediction suggests that presequences can be grouped into at least three clusters (Fukasawa *et al.*, 2015). The largest cluster (60% of presequences) shows typical presequence features such as the enrichment of arginines, almost no negatively charged residues, positively charged amphiphilicity, and the MPP cleavage pattern. On the other hand, the two remaining clusters differ from the classical view of presequences: Many of them have low net-charge and their cleavage sites did not match to any known patterns. Presequences belonging to these clusters should be the reason of the low prediction accuracy. To further improve the presequence prediction, it will be necessary to better characterize these untypical presequences.

Prediction of chloroplastic targeting signal

Approximately 3000 different proteins are estimated to be needed to develop a chloroplast. Similar to mitochondria, the vast majority of those chloroplast proteins are nuclear-encoded and imported into the chloroplast. Most chloroplast precursor proteins have a cleavable N-terminal extension, the chloroplastic targeting signal (transit peptide) (Li and Chiu, 2010; Paila *et al.*, 2015). Thus, existing chloroplastic targeting signal prediction tools deal with the cleavable N-terminal transit peptides. Precursor proteins containing the transit peptide are imported through the translocase in the outer and inner envelope membranes, the TOC and TIC complex, respectively. Similar to other N-terminal targeting signals, the transit peptide is cleaved off by the stroma processing peptidase during or after the translocation. Chloroplastic transit peptides exhibit a few characteristic features: A high content of

hydroxylated amino acids (e.g., serines), lack of negatively charged residues, and a propensity to form α -helical structures in hydrophobic environments (Bruce, 2001; Jarvis, 2008). In this respect, transit peptides are similar to mitochondrial presequences. Their cleavage sites are characterized by the higher frequency of Ala, Ile, Cys, and Val residues. A loosely conserved consensus motif ([V,I]X[A,C] ↓ A, where ↓ represents the cleavage site) was previously found from a limited set of 32 cleavage sites (Gavel and von Heijne, 1990). A more recent 198 cleavage site set gives three motifs, [V,I][R,A] ↓ [A,C]AAE, S[V,I][R,S,V] ↓ [C,A]A, and [A,V]N ↓ A [A,M]AG[E,D] (Savoijardo *et al.*, 2015).

A widely used prediction method for the transit peptide and its cleavage site is ChloroP (Emanuelsson *et al.*, 1999). However, predictors that are specialized for transit peptides are minor and the transit peptide prediction is usually integrated as a part of the prediction of N-terminal targeting signals: TargetP (Emanuelsson *et al.*, 2000), iPSORT (Bannai *et al.*, 2002), Predotar (Small *et al.*, 2004), and TPpred3 (Savoijardo *et al.*, 2015) are capable of predicting transit peptides. Indeed, TargetP includes ChloroP in its algorithm. Among those methods, TPpred3 achieves better performance for transit peptide prediction (46% precision and 64% recall) (Savoijardo *et al.*, 2015), although further improvement seems to be needed for practical purposes. Comparing with mitochondrial targeting signals, the data size of known transit peptides is smaller. Larger sets of established N-terminal proteomics data should be useful to further improve the prediction performance.

Prediction of nuclear localization signals and nuclear export signals

Nuclear proteins are carried into and out of the nuclei through the nuclear pore complex by nucleocytoplasmic transport receptors, that is, the importin (karyopherin)- β family. The human genome encodes 20 importin- β family proteins, of which 10 are nuclear import receptors (importin- β , transportin-1, -2, -SR, importin-4, -5 (RanBP5), -7, -8, -9, and -11), 7 are export receptors (exportin-1 (CRM1), -2 (CAS/CSE1L), -5, -6, -7, -t, and RanBP17), 2 are bidirectional receptors (importin-13 and exportin-4), and the function of RanBP6 is undetermined (Kimura and Imamoto, 2014). Those nucleocytoplasmic transport receptors are thought to recognize specific targeting signals on those cargo proteins. Nevertheless the targeting signals have been identified for only a few nucleocytoplasmic transport receptors, so far (Soniat and Chook, 2015): The classical nuclear localization signal (cNLS) for the importin- α adaptor, which links cargos and importin β (Lange *et al.*, 2007), PY-NLS for transportin-1 and -2 (Lee *et al.*, 2006), the NES for exportin-1/CRM1 (Hutten and Kehlenbach, 2007), and the SR-rich domain that binds to transportin-SR (Maertens *et al.*, 2014). Among those nuclear targeting signals, cNLS and NES are well characterized. Thus, recent prediction algorithms for NLSs and NESs mainly target the two types of the signals.

cNLSs include two types of signals, the monopartite and the bipartite NLSs: The monopartite NLS means a single cluster of basic amino acid residues (e.g., KR[K/R]R and K[K/R]RK) and the bipartite NLSs means two clusters of basic amino acids separated by a 10–12 amino acid linker (e.g., KRX_{10–12}K[K/R][K/R]) (Kosugi *et al.*, 2009). NucPred (Brameier Krings and MacCallum, 2007), cNLSmapper (Kosugi *et al.*, 2009), NLSstradamus (Ba *et al.*, 2009), NucImport (Mehdi *et al.*, 2011), and seqNLS (Lin and Hu, 2013) are widely used for the cNLS prediction. According to a recent assessment based on experimentally identified human NLSs (77% of them are classified as known cNLSs) (Lisitsyna *et al.*, 2017), the highest Matthews' correlation coefficient (~ 0.3) was obtained from NucPred, seqNLS, and NLSstradamus. However, those prediction methods correctly identified only $\sim 45\%$ of the human NLS data, suggesting the necessity for further improvement on the NLS prediction. Recent proteomic analysis for the identification of cargo proteins of 12 nucleocytoplasmic transport receptors (10 nuclear import receptors and 2 bidirectional receptors) (Kimura *et al.*, 2017) would be a valuable resource for further improvement of NLS prediction and/or for finding novel NLSs. Meanwhile, the proteomic analysis pointed out that about 30% of the identified cargos are shared by multiple receptors. Better characterization of such multiple recognitions may be fruitful for future improvements.

Nuclear export receptor exportin-1/CRM1 binds to 8–15 residue-long NESs in hundreds of distinct cargos. NES sequences are diverse and 11 patterns were defined by a peptide library-based study and structural analyses of exportin-1/CRM1-NES (Kosugi *et al.*, 2008; Fung *et al.*, 2015, 2017). Those NESs usually have 4–5 hydrophobic residues, which bind to the hydrophobic pocket of the receptors. The hydrophobic residues are arranged in various patterns: $\Phi X_3 \Phi X_2 \Phi X \Phi$, $\Phi X \Phi X_2 \Phi X \Phi$ and $\Phi X_2 \Phi X_3 \Phi X_2 \Phi$ (Φ represents Leu, Val, Ile, Phe, or Met). Several computational tools, such as NetNES (La Cour *et al.*, 2004), NESsential (Fu *et al.*, 2011), NESmapper (Kosugi *et al.*, 2014), LocNES (Xu *et al.*, 2014), and Wregex-based prediction (Prieto *et al.*, 2014) have been developed to predict NESs, based on the sequence profiles of NESs and some biophysical properties (e.g., disorder propensity and solvent accessibilities). However, the performance of those predictors is still not enough (precision is $\sim 50\%$ with 20% recall). The diverse NES patterns and the low performance of predictors suggest that there may be no fixed hydrophobic pattern in NESs. There may be a limitation to predict NESs from only sequence. Combination with structure-based predictions might help to find a breakthrough.

Other signals

Besides the above signals the predictors of which are relatively well developed, there are also known signals that may be used for the prediction. Here, we briefly sketch several of them.

As noted above, peroxisomes are often not included in the prediction repertory because known peroxisomal proteins are not so many. However, two kinds of signals, namely PTS1 and PTS2, are known to exist. PTS1 is characterized by the presence of the SKL motif (the more precise consensus is [SAC][KRH][LM]) in the C-terminus of proteins and is recognized by the receptor Pex5, which is a modular protein containing a C-terminal tetratricopeptide repeat domain (Gould *et al.*, 1987; Kim and Hettema, 2015). Of course, its computational recognition is easy. It is also possible to include weaker conserved patterns near PTS1. However, the number of proteins that are sorted with PTS1 in vivo is not enough to make the prediction of the entire peroxisomal proteins

reliable. The other signal, PTS2, is recognized by the receptor Pex7. The signal is characterized as an about nine-residue motif near the N-terminus; the consensus motif is R[LIVQ]XX[LIVQH][LSGA]X[HQ][LA] (Petriv *et al.*, 2004). But its reliable predictors have not been developed because of its small sample size, again.

It has been shown that some lysosomal proteins are recognized from their special modification with mannose-6-phosphate (M6P), allowing their recognition by M6P receptors in the Golgi complex and ensuing their transport to the endosomal/lysosomal system (Braulke and Bonifacio, 2009). However, their sequence determinant is still a mystery and thus there have not been effective predictors for lysosomal proteins, so far.

Similarly, some other posttranslational modifications can affect the localization of proteins significantly. Typical examples are lipid anchors, where attached lipid moiety is inserted into the membrane as an anchor. Three types of lipid anchors are known: N-myristoylation, glycosylphosphatidylinositol (GPI) attachment, and prenylation. In N-myristoylation, a 14-carbon fatty acid is attached to an N-terminal Gly residue (the consensus motif is MGXXX[ST]) (Johnson *et al.*, 1994). GPI is covalently attached to the C-terminus of proteins (Ferguson *et al.*, 2009). In prenylation, a 15-carbon (farnesylation), or a 20-carbon (geranylgeranylation) lipid is attached to a cysteine by farnesyltransferases or by protein geranylgeranyl transferases I, respectively (the consensus motif is CAAX at the C-terminus) (Fu and Casey, 1999). For each of them, prediction algorithms, such as NMT (Maurer-Stroh *et al.*, 2002), PredGPI (Pierleoni *et al.*, 2008), GPS-Lipid (Xie *et al.*, 2016), have been developed (Audagnotto and Dal Peraro, 2017). However, distinctions on which membrane the predicted lipid will be targeted might be necessary in the future when enough data for each membrane are accumulated.

For the prediction of the localization membrane for (integral) membrane proteins, the prediction of their membrane topology is also important because it is known that some important signals can exist on the so-called cytoplasmic tail (i.e., the terminal region that is protruded to the cytoplasmic side with a membrane) of membrane proteins. For the prediction of membrane topology itself, please refer to its specific article. Here, we would like to point out just two things: The prediction of membrane topology can be related to the prediction of the cleavage of N-terminal hydrophobic segment because N-terminal transmembrane segments are often wrongly predicted as cleavable signal peptides, as explained above. Second, the most important localization signal existing on the C-terminus of a protein, which also exists as a part of the cytoplasmic tail, is known as the KDEL signal, which works as a retention signal to the ER (Munro and Pelham, 1987). Again, its computational recognition is not so difficult, though there are some differences in the optimum motif between organisms, such as HDEL in yeasts. However, the distinction of ER membrane proteins from the others remains to be a very difficult prediction problem because the KDEL signal is not so universal.

For some of the proteins localized at relatively minor sites, such as the Golgi body and the cell wall (in yeasts and plants), there have been several reports on their potential signals (Banfield, 2011; Mao *et al.*, 2008) but their known examples are too few to be tested in the scheme of machine learning.

Concluding Remarks

When publishing a paper on a new prediction method, it is generally required that the method should outperform existing ones. Indeed, many recent papers in the field of protein localization prediction claim that their predictors are apparently quite reliable. However, as far as the amino acid sequence is used as its input, it is questionable if these predictors can be practically useful for totally new proteins. It seems to be a fundamental problem that we do not know how many nuclear DNA-encoded proteins are sorted with their own amino acid sequence signals. Thus, perhaps, a promising new direction in this field would be to use prediction tools to evaluate the possibility of whether each protein is sorted with a classical pathway or not. On the other hand, it is certain that the practical importance of subcellular localization prediction would become even less with the future accumulation of more systematic and precise proteomic data. Then, what new directions will be pursued? As mentioned above, one possibility is to develop a more precise predictor that can predict the semiquantitative distribution between multiple sites. To do this, more comprehensive data for localization are necessary. Although this is not the scope of this article, the prediction of subcellular localization for RNAs would also be an interesting frontier. Finally, we believe that the field should be extended to more general goals. Three possibilities in this direction would be (1) to explore the possibility of predicting differential localization of a protein between different cell types/conditions, incorporating the information of protein isoform expression between cells/conditions; (2) to explore the possibility of more general prediction of protein *in vivo* fates, including the predictions of more general post-translational modifications and degradations; and (3) to explore the possibility to develop predictors for artificial proteins, incorporating a vast amount of synthetic biological data. Such predictors will have some practical value for designing new drugs, for example, that are optimized to be targeted to a certain localization site.

Introduction

Proteomics sets the ambitious challenge of the large-scale determination of gene and cellular function directly at the protein level. As suggested in a Nature Methods Commentary: “Sequencing the human genome was perhaps the easy part, and now making sense of the constantly moving and changing picture of the proteome will require a lot of time, effort and creativity” (Nilsson *et al.*, 2010). Proteomics has thus evolved as a multidisciplinary field relying on both traditional analytical methods and the development of new technologies. Considering that in complex mixtures proteins may span up to 12 orders of magnitude in relative abundance (Angel *et al.*, 2012), reliable profiling of protein expression is obviously not straightforward.

More generally, the elucidation of biological processes requires information on protein abundance, amino acid variations and modifications, as well as interacting partners. Proteomics large-scale studies undertaken to collect this information roughly span four main objectives: (1) identification of all proteins from a cell or tissue creating a catalogue of information; (2) analysis of differential protein expression associated with specific conditions, different cell states and sample treatments; (3) characterisation of proteins by discovering their function, cellular location, posttranslational modifications (PTMs), etc and (4) contribution to understanding protein interaction networks. When met, these are useful to design effective diagnostic techniques (Liu *et al.*, 2013) or means of monitoring plant growth (Baginsky, 2009).

The present article is introductory to Robin (2018) and Bilbao (2018) where details of the relevant proteome databases and tools are provided. This trilogy is intended as explanatory for the common terminology found in the dense and sometimes cryptic data analysis paragraphs of the Material and Methods section of published proteomics studies.

Proteomics Technical Issues Bearing on Data Processing

The major steps leading to the generation of proteomics data involve sample preparation, molecule separation and mass measurement. Despite its paramount importance in the outcome of a proteomics experiment sample preparation cannot be detailed or discussed here. This information is nonetheless accounted for in the “Minimum Information About a Proteomics Experiment” (MIAPE, (Taylor *et al.*, 2007)) standard with which any stored experimental dataset must comply in proteomics data repositories (see Robin, 2018). Techniques for molecule separation and mass measurement are now introduced briefly in relation to the questions raised by their automation.

Separation Techniques

Technical means to separate complex mixtures have been and still are a central concern in physics and chemistry. The physico-chemical properties of biological molecules account for the common use of electrophoresis and liquid chromatography in molecular biology.

The major difference in using one or the other techniques in the proteomics workflow is the position of the protein digestion step in the overall process. Proteins are separated by 2D-gel electrophoresis, excised from the gel and then digested so as to feed the mass spectrometer whereas proteins are digested prior to running the chromatographic separation that is coupled to the mass spectrometer.

2D-gel Electrophoresis and image processing

Under the influence of an electrical field, charged molecules migrate in the direction of the electrode bearing the opposite charge. Because of their varying charges and masses, different molecules will migrate at different speeds and will thus be separated into single fractions. Such a principle defines electrophoresis.

The electrophoretic mobility, which influences the speed of migration, is a significant and characteristic parameter of a charged molecule. The electrophoretic separation of samples is done in a buffer with a precise pH value and a constant ionic strength. Proteins are separated in two dimensions: mass and pI (isoelectric point). On gels they are not visible and various staining methods are used for detection. Proteins are revealed on a 2D-gel as spots of various sizes and intensity that correspond to protein abundance (darker spots for more abundant proteins).

An image capture of a 2D-gel can be analysed by software to assist spot picking by a robot and/or identify differentially expressed proteins. Gel suppliers often support 2D-gel analysis software most of which is licensed. The two commonly used tools are SameSpots (see “Relevant Websites section”) and ImageMaster/Melanie (see “Relevant Websites section”). They have been developed over decades. The first version of SameSpots was called Phoretix 2D (Mahon and Dupree, 2001) and Melanie was popularised in Appel *et al.* (1991). Despite their respective good performance, both tools still stumble on the inherent ambiguity of faded spots. Other algorithmic issues hindering 2D-gel qualitative and quantitative comparison are well explained in Dowsey *et al.* (2010).

Digitalised 2D-gels have been annotated and stored in on-line databases for comparative and benchmarking purposes. Many of these were created in the 1990s and are no longer maintained. The reference database remains World 2D-page (see "Relevant Websites section") and more recently the GelMap portal was initiated for plant species (see "Relevant Websites section").

Although many hundreds and even thousands of proteins can be separated on a 2D-gel, this technique remains less popular in high-throughput settings despite notable attempts such as Dowsey *et al.* (2008). Nonetheless, 2D-electrophoresis cannot be ignored as a useful approach for instance to assess the extent of protein forms in a given sample and tends to be considered as a complement to the popular Liquid Chromatography (LC)-based proteomics (Rogowska-Wrzesinska *et al.*, 2013).

Liquid chromatography and retention time prediction

Liquid Chromatography (LC) utilises a liquid mobile phase to separate the components of a peptide mixture. A liquid medium continuously flows through a chromatographic column and carries the analytes. The chromatographic separation process is based on the difference in the surface interactions of the analyte and eluent molecules. The velocity at which individual molecules in the mixtures move through the column is a function of the physical property of the analytes, the content of the column and the composition of the mobile phase. Chromatograms are output as plots of the retention time (duration from tip to bottom of the column) in the x-axis and compound abundance in the y-axis. The most popular technique in proteomics is the reverse-phase chromatography. Although reproducible, small variations are observable in these plots as a reflection of peptide conformational changes among others.

The hydrophobicity of peptides is highly correlated to retention time. Due to surface interactions, hydrophobic peptides tend to stay longer in the column. However the sole consideration of this property is not enough to accurately predict retention time from the peptide amino acid sequence. The long path to designing an efficient method is well described in Henneman and Palmblad (2013) where the many attempts with mixed results and performance are referred to in a timeline starting in 1951. Furthermore, the comparison of different methods for retention time prediction has often not led to a consensus in the metric to be used in the evaluation of the accuracy of prediction. As very nicely put by Henneman and Palmblad (2013), discussions centred on the (non)-linearity of the model and variations of the tolerance to error are pointless when the need for assigning a confidence interval to a predicted retention time is prevalent. Another excellent review of peptide retention time prediction methods can be found in Moruz and Käll (2017) where the contribution of prediction is shown (i) to improve peptide identification in simple mixtures by matching theoretical and observed masses and retention times (ii) to increase the throughput of proteomics experiments or (iii) to decrease the number of candidate peptides during database searching.

Interestingly, software designed for 2D-gel image analysis was transposed in the 1990s to LC-MS images defined as plots of mass versus retention time mainly for quantitative studies. Algorithmic aspects of the associated software are reviewed in Dowsey *et al.* (2010).

Ion mobility

Ion mobility (IM) is a fast and reproducible technique for separation of molecules based on their size and shape. Molecules having the same mass-to-charge ratio, but different conformational arrangements can be distinguished. IM has been and is used in combination with LC and mass spectrometry (see next section), providing an additional dimension of information with benefits for proteomics analyses (Baker *et al.*, 2015). The following list of software supports IM data processing: Synapter (Bond *et al.*, 2013), LC-IMS-MS FeatureFinder (Crowell *et al.*, 2013), ISOQuant (Distler *et al.*, 2014) and Skyline (Pino *et al.*, 2017).

While IM has shown great utility when coupled with MS for analysis of complex samples, methods for processing the complex data generated still lag behind. In fact, the incorporation of this extra separation dimension requires upgrades and optimisation of existing computational pipelines and the development of new algorithmic strategies to fully exploit the advantages of the technology.

Mass Spectrometry

A mass spectrometer produces charged particles (ions) from the molecules to be analysed, in the case of proteomics, peptide mixtures. Various means are implemented in the spectrometer to exert forces on the charged particles and measure the mass or molecular weight of the analysed substance.

From raw data to peak lists

All mass spectrometers carry out three distinct functions:

1. *Ionisation* for charging peptides; the major two processes are Electrospray Ionisation (ESI) and Matrix-Assisted Laser Desorption Ionisation (MALDI). These techniques are detailed in all basic mass spectrometry (MS) manuals.
2. *Ion analysis* for separating ions by mass; the different analysers in proteomics are Time-Of-Flight (TOF), Quadrupole, Ion Trap, Fourier Transform Ion Cyclotron Resonance (FTICR). These techniques are detailed in all basic MS manuals.
3. *Ion detection* that requires the collection of ions of different masses. The charged ion beam generated by the analyser is directed sequentially (point) or in parallel (array) onto a point/array collector. This causes an electric current the flow of which marks the arrival of successive ions and the magnitude of which marks their abundance. The analogue electrical signal is digitised and processed by a computer.

Fig. 1 (a) Typical MALDI-TOF spectrum, (b) Relationship between dimensions m/z , intensity, retention time. Source: https://en.wikipedia.org/wiki/File:Liquid_chromatography_MS_spectrum_3D_analysis.png.

A mass spectrometer outputs raw mass spectra featuring the mass-to-charge ratio (m/z) in the x-axis and the intensity in the y-axis (Fig. 1).

In theory, the mass of each peptide should correspond to a peak in the spectrum. In reality, the imperfection of the sample, its handling and processing, etc., introduce a background noise and cause variations in intensity. The selection of the relevant peaks, that is, those definitely corresponding to peptide masses, is not straightforward. The most intense peak in an isotopic group is not necessarily the monoisotopic mass of a peptide. The intensity ratio of all peaks in this group must be examined. Moreover, a spectrum may contain single- and double- or triple-charged species. Indeed, a population of variably charged ions is generated in the ionisation process. In a given population, peptides may have 1, 2 and 0 sites of protonation. In this case, the intensity of the peaks is a reflection of the population generated in the ionisation process. Multiple-charged ions are generally of low abundance in MALDI but frequent in ESI. At sufficient resolution, a single-charged ion will show isotopic peaks that differ by 1 mass unit, a double-charged ion will show peaks that differ by 0.5 mass units and so on.

Despite these objective difficulties, peak detection is automated. Many solutions are proprietary and integrated in software licensed with an instrument. OpenMS (see “Relevant Websites section”) detailed in Bilbao (2018) is a popular software library implementing a wide range of useful functions for MS data analysis. It includes for instance, peak detection which main task is centroiding. According to the most recent IUPAC recommendations (Murray *et al.*, 2013) centroiding spectra entails calculating the centroid based on the average m/z value weighed by the intensity, and assigning m/z values based on a calibration file (Internal calibration consists in running a well-known sample, detect the signals, and use a correction function to associate the known values to the experimentally measured values. It is a recalibration step that corrects the experimental data with the use of information in the same spectrum. Once the correction is made, the instrument can update its hardware parameters accordingly. Regular calibration of the m/z scale is necessary to maintain accuracy in the instrument.). Only the centroid m/z value and the peak magnitude are stored. This is the basis of peak lists that are input in the various software tools that identify proteins from mass spectra. Another popular open software library for performing basic mass spectra processing converting raw data to peak lists is ProteoWizard (see “Relevant Websites section”). As OpenMS, its major advantage is that it is instrument independent and provides tools to convert vendor proprietary formats to standard and open formats (Robin, 2018; Bilbao, 2018).

Inherent Role of Bioinformatics in Proteomics

In 1993, five independent groups published on a method for protein identification using mass spectrometry (MS) referred to as Peptide Mass Fingerprinting, shortened as PMF (Henzel *et al.*, 1993; James *et al.*, 1993; Mann *et al.*, 1993; Pappin *et al.*, 1993; Yates *et al.*, 1993). Each of these was integrating software to match a list of experimentally observed peptide masses with theoretical peptide masses computed from protein sequences stored in a selected database. This computation is fairly simple given the known monoisotopic mass of each of the 20 amino acids. By definition, the mass of a peptide is the sum of masses of the amino acids it is made of.

This protein identification technology relies heavily on the fast and accurate mapping of mass spectra to protein database entries, and gave birth to a bioinformatics discipline focusing on the development of software tools for the processing of MS data (proteome informatics). Several software tools implementing this *Peptide Mass Fingerprinting* (PMF) identification were developed in the following years such as Perkins *et al.* (1999) the seed of the most popular Mascot software (see Bilbao, 2018).

Soon after, the first publication on another MS based approach for identifying proteins emerged, tandem MS or MS/MS (Eng *et al.*, 1994). In this setup the mass spectrometer performs sequential MS analyses. In a first stage intact peptides are analysed and a mass spectrum is produced. Next, a selection of these peptides is fragmented at the peptide bond by bombarding them with fast-moving atoms. The mass and intensity of each peptide fragment is detected producing a MS/MS spectrum. Each MS/MS spectrum can be mapped to its originating peptide using a similar approach to PMF, where the assembly of peptide fragment masses making up the mass spectrum is screened against theoretical peptide fragment masses. Technically, the workflow can be

fully automated: digested peptide mixtures are run through LC, then upon elution from the chromatographic column the analytes are ionised and directly sprayed into a first mass spectrometer, where they are measured. The resulting spectrum provides the mass to charge (m/z) ratio of the intact analyte ions (precursor ions) that are coming off the LC. The ions of a precursor are selected, and fragment ions are created and measured in a second mass spectrometer to produce the MS/MS spectrum for the analyte. This approach was called *shotgun proteomics* (Wolters *et al.*, 2001) referring to earlier *shotgun genomics*, which led to sequencing the first human genome, as a means to boost the field to the high-throughput level.

Early automation: Shotgun proteomics

From the turn of the 21st century, mass spectrometry combined with liquid chromatography has quickly become a central analytical platform for the high-throughput investigation of complex protein samples (Aebersold and Mann, 2003). MS instrumentation with higher resolving power and mass accuracy, increased sensitivity, alternative fragmentation mechanisms and new data acquisition strategies has boosted the throughput, quality and depth of proteomics data. At the same time, the ability to quickly and consistently analyse the large amounts of experimental data produced in proteomics research has relied on software advances well reviewed in Nesvizhskii (2010) and illustrated in Bilbao (2018).

Over the years, bioinformatics has emerged as a crucial contributor with the development of algorithms, the connection of various tools into pipelines, as well as the deposition and dissemination of both software and data. Currently, the prominence of open source software and public data in reproducible research is emphasised and clearly details in both aspects of software in Bilbao (2018) and public data in Robin (2018).

Fragmentation techniques

Tandem mass spectrometry (abbreviated MS/MS) consists in determining the masses of selected ions. In MS/MS, a precursor or parent ion is mass-selected and fragmented and the masses of the resulting product or daughter ions are analysed. Some peptides are further analysed to determine their precise amino-acid content. The technique requires either two or more analysers in series or relies on the intrinsic characteristics of some spectrometers such as the MALDI-TOF. When several analysers are involved, precursor ions are separated according to their m/z value in the first analyser and selected for fragmentation. Fragments are analysed in a second analyser.

Different types of fragment ions observed in an MS/MS spectrum depend on the peptide primary sequence, the amount of internal energy, how the energy was introduced, the charge state, etc. Fragment ions are named according to an accepted nomenclature first proposed by Roepstorff and Fohlman (1984), and modified by Johnson *et al.* (1987). It is represented in the Fig. 2

The most common ions observed in peptide mass spectra are a , b , and γ . The a type ions occur at a lower frequency and abundance compared to the b and γ type ions. The a - b pairs are often observed in fragment MS/MS spectra. The presence of such pairs can then be used for the detection of b ions.

The most commonly used peptide fragmentation techniques are:

- Collision-Induced Dissociation (CID).
- Electron-Capture Dissociation (ECD).
- Electron-Transfer Dissociation (ETD).

In CID, molecular ions are fragmented in the gas phase (Mitchell Wells and McLuckey, 2005). In this case, the molecular ions are pushed to collide with neutral molecules such as helium, nitrogen or argon. Collision induces kinetic to internal energy transfer. The transfer of energy results in bond breakage so that ions are split into smaller fragments. CID most often leads to the generation of b and γ type ions. Note that Higher-energy Collisional Dissociation (HCD) often cited in the literature is a CID technique specific to a particular type of mass spectrometer, namely the Orbitrap which principle was introduced in Makarov (2000).

In ECD, molecular ions are fragmented by the direct introduction of low energy electrons to trapped gas phase ions (Zubarev *et al.*, 1998). During ECD, the parent ions capture single electrons and fragment simultaneously. In such case, the

Fig. 2 The a, b, c ions extend from the N-terminus while x, y, z ions extend from the C-terminus. Source: https://commons.wikimedia.org/wiki/File:Peptide_fragmentation.gif

fragmentation occurs also in the positions that are not energetically favoured. This generates more complete ions series, most often *a*, *c* and *z* type ions.

ETD is another technique to fragment molecular ions in the gas phase (Syka *et al.*, 2004). Similar to ECD, ETD induces fragmentation of peptides by transferring electrons to them. ETD cleaves randomly along the peptide backbone while side chains are left intact. The technique works well for higher charge state ions ($> +2$) generating *c* and *z* type ions. ETD is advantageous for the fragmentation of longer peptides or even entire proteins.

Tandem MS provides structural information by establishing relationships between precursor ions and their fragmentation products.

Data Processing

A tandem (MS/MS or MS2) mass spectrum is composed of a precursor peptide and a combination of fragment peaks produced from the fragmentation the peptide sequence. The number of peaks may vary from ten to several hundreds. The peak of a MS/MS spectrum is characterised by the same two values as the MS1 spectrum: mass-to charge ratio (m/z) in its intensity (abundance).

Peptide identification relies on matching peaks from MS/MS spectra with either theoretical or reference experimental spectra. Software for performing this task is detailed in Bilbao (2018). Generally, it first entails the *in silico* digestion of protein sequences into peptides in accordance with the cleavage rules of the protease used in the sample preparation step of the experimental workflow. Then, for each peptide a theoretical spectrum is generated and the calculated peptide fragments are compared with the experimentally observed peaks. A peptide match score is derived which reflects the similarity between the MS/MS spectrum and the theoretical peptide spectrum. This aspect is detailed in the next section.

This type of analysis has been extensively reviewed in the literature where different algorithmic solutions are described in terms of finding the optimal Peptide Spectrum Matches (PSMs). The need to optimise arises from a variety of situations inherent to mass spectrometry. An MS/MS spectrum contains peaks that cannot be assigned to backbone fragments. Possible sources of these peaks include neutral losses, side chain fragments and ions due to multiple backbone fragmentations. Other challenges include ambiguous co-fragmented peptides and frequently missing fragment ions at the beginning or the end of a peptide sequence.

Manually or automatically annotated MS/MS spectra are commonly displaying the *ion ladders* reflecting the ion nomenclature as shown in the figure below where peaks matching an ion series are labelled (Fig. 3).

PSM Scoring and Validation of Protein Inference

A number of different scoring functions have been described in the literature including simple spectral correlation functions such as the dot-product (Liu *et al.*, 2007), more advanced cross correlation functions, scoring functions based on empirically observed rules or statistically derived fragmentation frequencies. The score reported for a given PSM can be on some arbitrary scale or converted to a statistical measure such as a p-value or an expectation value, E-value. The final list of identified peptides is compiled into a protein 'hit list', which is the output of a typical proteomics experiment

Several properties can contribute to scoring the similarity between an experimental spectrum and a reference. The precursor mass is mainly used to restrict the search space. The mass differences for both the matching fragments and the precursor are usually considered in the scoring. Other properties include the number and intensities of the experimental peaks, number of complementary ions, number of missed cleavages and number (and types) of modifications.

A great variety of scoring strategies have been proposed for peptide identification. Broadly speaking, they can be divided into heuristic and probabilistic schemes. Heuristic methods typically combine a set of scoring properties in a practical form reflecting expert knowledge. A product or a linear function are simple examples of how these properties can be combined into a scoring function. Probabilistic schemes compute the probability that a given sequence is the origin of the spectrum.

Fig. 3 Example of annotated spectrum that shows the ion ladders (*y* and *b* series) reconstituted for peptide GISHVIVDEIHER. Reproduced from Hernandez, P., *et al.*, 2006. Automated protein identification by tandem mass spectrometry: Issues and strategies. *Mass Spectrom. Rev.* 25 (2), 235–254.

The “target-decoy” approach is commonly used for estimating the false discovery rate (FDR) (Elias and Gygi, 2007). A target-decoy database consists of all sequences to be used in the identification process plus the same amount of decoy sequences. For each sequence entry in the database, a ‘matching’ decoy entry is produced by either reversing the original sequence or by shuffling the letter code. Seemingly counterintuitive, searching against a larger search space decreases the number of reliable identifications because of the higher probability of retrieving false positives.

De Novo Sequencing

De novo sequencing algorithms attempt to derive a peptide sequence directly from the MS/MS spectra by considering the mass difference between pairs of peaks and all possible amino acid combinations (longest ion ladders). The “peptide sequence tag” algorithm was a stepping-stone in the implementation of the identification process (Mann and Wilm, 1994). It is based on extracting short unambiguous amino acid sequences from the spectrum peak pattern by linking two peaks with a mass difference corresponding to the mass of an amino acid. In theory the full peptide sequence can be found using an algorithm based on tag-extraction by finding a tag spanning the full mass range of the spectrum. The approach seemed well suited to solving *de novo* sequencing. However, the accuracy of such algorithms hinges on very high quality spectral data and therefore remains limited to sequencing a small amount of peptides. In practise, sequence tags in combination with the spectrum precursor mass information have been used as a specific probe to identify the peptide origin of the MS/MS spectrum.

Many algorithms have been published whether dependent on dynamic programming, integer linear programming, machine learning and a few other modelling techniques. The coverage, the description and the evaluation of software solutions is provided in Muth and Renard (2017) where all methods that were published were tested. In the end, only a handful remains operational and usable with any type of fragmentation data. Only two of these are open (Frank and Pevzner, 2005; Ma, 2015). Interestingly, the most convincing application of this software so far is antibody sequencing (Tran *et al.*, 2016; Guthals *et al.*, 2017) which brings out sequence polymorphism independently of DNA sequencing. Such an alternative method is helpful since an individual antibody repertoire cannot be predicted from the genome alone.

Identification and Localisation of Post-Translational Modifications

At this point, it is probably important to note that only a minority of spectra are actually assigned to peptides when processing data. In fact, the vast majority, that is at least 60% of spectra produced by the mass spectrometer remain unassigned and this is sometimes called “proteomics dark matter” (Skinner and Kelleher, 2015). This substantial unidentifiable portion of the data is often thought to be attributable to our poor knowledge of Post-Translational Modifications (PTMs). PTMs are alteration of proteins during or after protein biosynthesis, resulting in changes of the protein physicochemical properties, which modulate and regulate cellular functions. Abnormal PTM abundances are involved in disease states.

By identifying the occurrence of regular mass shifts corresponding to the addition or removal of chemical groups of known masses in a peptide MS/MS spectrum, it is possible to identify a PTM and its position on the peptide sequence. When specified in the search parameters, search engines can consider relevant PTMs, such as phosphorylation. However, this number is usually limited because the search space is substantially expanded.

Exhaustive identification of PTMs in high-throughput MS-experiments has proven to be difficult for a number of reasons including the large number of possible PTMs, sub-stoichiometric amounts of modified proteins, and as peptides carrying certain PTMs display MS2 fragmentation patterns which can be difficult to interpret (Creasy and Cottrell, 2004). Therefore successful protein modification studies rely on carefully designed experimental setups applying extensive sample fractionation/enrichment protocols for the detection of low abundant protein species. MS data need to be accurate and contain information rich fragmentation patterns. Software for PTM automated detection is detailed in Bilbao (2018).

It was proposed to rename modified proteins into proteoforms (Smith *et al.*, 2013) or modforms (Prabakaran *et al.*, 2012) suggesting that protein-protein interactions should actually be described as *form-*form interactions as pointed out in Chichester *et al.* (2003).

Proteomics Workflows

In this section, the impact of the technical and experimental choices on data processing and analysis is reviewed.

Database Versus Spectral Library Search

As explained in Section “Proteomics Technical Issues Bearing on Data Processing”, the fragmentation pattern encoded by a tandem (or MS/MS) spectrum supports the identification of the corresponding peptide sequence. Search engines annotate the MS/MS spectra with peptide sequences using various algorithms and scoring strategies (Nesvizhskii, 2010). Even though database search engines remain very popular, a significant number of articles promote the use of direct spectral matching and the construction of spectral libraries to support reliable peptide identification and quantification especially in high-throughput settings (Lam *et al.*, 2007). Computationally, using spectral libraries is also much more efficient as it skips the construction of theoretical spectra. The

downside is of course, the potential incompleteness of the library and its subsequent limited coverage. Nonetheless, the constant improvement of instrument accuracy and sensitivity goes along with the potential for generating libraries with good coverage.

In database search, protein sequences are digested *in silico* into peptides. Considering knowledge about the type of fragmentation technique employed, theoretical spectra are generated from each peptide sequence. The search engine then scores the observed tandem mass spectra by matching against the predicted fragmentation, producing a list of peptide-to-spectrum matches (PSMs).

Spectral library searching offers a natural way of incorporating previous knowledge about observed peptides and their respective fragmentation patterns into a new search. The National Institute of Standards and Technology (NIST, see “Relevant Websites section”) and the Institute for Systems Biology (ISB, see “Relevant Websites section”) have invested effort in compiling high quality publicly available spectrum libraries for different organisms and instrument types including some specialised libraries rich in modified peptides. Spectral libraries generated from previously annotated spectra can be used as reference to further annotate new generated spectra, producing a list of spectrum-to-spectrum matches (SSMs).

To enable the exploration of these spectral libraries when analysing new experimental data, several tools have been developed (Griss, 2016). Firstly, peptide identification with these tools is fast as the experimental data is screened against small size databases and the time-consuming modelling of theoretical spectra can be skipped. Secondly, a library spectrum is rich in information (including fragmentation intensities of a wide range of fragment ions) relative to a theoretical peptide spectrum. Finally, library search tools typically employ simple and fast scoring algorithms and are expected to yield more discriminative match scores than sequence search tools. The main drawback remains the impossible identification of peptides, which are absent in the library. Note that decoy spectral library tools have been developed to evaluate the quality of spectral matching based on an FDR calculation. These are reviewed in Zhang *et al.* (2018).

A particular representation spectral data is in the form of spectral network in which spectral similarity is mapped (nodes are spectra and edges are similarity between spectra as measured by peak alignment). As noted in Guthals *et al.* (2012), the spectral network paradigm is founded on two core principles beyond mainstream approaches: (1) matching unidentified spectra to a spectral library or to other unidentified spectra is more efficient than to theoretical spectra based on reference sequences and (2) consensus interpretation of sets of related spectra is more reliable than identification of one spectrum at a time.

At this point in time, the consensus view when comparing the much more frequently used database search to spectral library matching is that each corresponding output complements each other. The combination of both strategies tends to increase the number of confidently identified peptides and proteins.

Data Dependent Acquisition (DDA) Versus Data Independent Acquisition (DIA)

In shotgun proteomics, the selection of precursor ions in mass spectra (MS1) for fragmentation that will produce tandem mass spectra (MS2) is defined upon intensity. In other words, the ten or twenty (parametered choice) most intense peaks designate which peptide will be fragmented. To make this choice less dependent on the data and somehow less arbitrary, a new approach called “Data Independent Acquisition” (DIA) was introduced contrasting to “Data Dependent Acquisition” (DDA) by means of co-selection and co-fragmentation. DIA is by design avoiding the detection and selection of individual precursor ions during LC-MS analysis.

An early DIA proof-of-principle was reported in Purvine *et al.* (2003). Then Venable *et al.* (2004) suggested the use of sequential isolation and fragmentation of several precursor ion windows (10u each) using a linear ion trap over a defined mass range, thereby introducing the term “data-independent acquisition”. DIA integrates qualitative and quantitative information. Recorded spectra are a continuous map of multiplexed chromatographic profiles from all detectable peptides, which are eluted, ionized and fragmented. As a consequence of this parallel peptide analysis, one of the main challenges to perform identification in DIA spectra is the lack of a direct relationship between each precursor ion and its fragment ions, as opposed to DDA. The most straightforward way to process DIA spectra is the direct submission to DDA search engines. This topic is well covered in Bilbao (2018).

Overall, DDA performance declines as sample complexity increases because the semi-stochastic selection of precursor ions aggravates known limitations for both identification and quantification: limited reproducibility and dynamic range, bias toward high abundance peptides and under-sampling to name a few. In turn, DIA solves these issues while generating highly convoluted, dense and redundant datasets that remain challenging to analyse.

Top Down Versus Bottom up MS

Shotgun proteomics and other strategies that emerged with the increasing resolution power of mass spectrometers are still facing with challenges of protein information loss resulting from the ambiguity of the peptide reassembly process into proteins. To begin with, identified peptides are often not specific to an individual protein and even less to a protein form, which may lead to piecing together chimeric proteins. Secondly, significant portions of a protein may not be identified, for instance due to the absence of lysine or arginine and the oversized peptides generated by tryptic digestion. Consequently, potential meaningful PTMs or sequence variants occurring in these regions cannot be detected.

So far in the present article, all approaches have been based on breaking proteins into pieces (peptides and peptide fragments). The generic term for qualifying these is “bottom-up” proteomics. In recent years, “top-down” proteomics has emerged as an answer to the shortcomings just listed. In this set-up, the intact protein is introduced into the mass spectrometer where both intact and fragment ions masses are measured. Taking advantage of high resolution and mass accuracy, Top Down proteomics studies

have largely been implemented using ESI coupled to either Fourier transform ion cyclotron resonance (FT-ICR) or Orbitrap mass analysers. These approaches are well reviewed in [Catherman et al. \(2014\)](#).

The most renowned software for the identification of intact proteins is ProSight which latest version is defined as light ([Fellers et al., 2015](#)). It uses the precursor mass and a mass tolerance window to generate a possible list of candidates from a larger annotated database. The theoretical fragment ions from the candidates are then compared to the experimentally determined fragment ions within a fragment mass tolerance. A P-score is calculated for each hit, representing the probability that a random sequence could account for the matching ions. ProSight versions were gradually improved to include fixed (e.g., alkylation of cysteine residues) and terminal (e.g., N-terminal acetylation) modifications. An alternative to ProSight is mainly BIG Mascot or MascotTD, based on the popular Bottom Up software platform Mascot and extends the precursor mass cutoff from 16 kDa to 110 kDa (see “Relevant Websites section”).

To be complete, the term “middle-down” proteomics should also be defined in this section. This approach generates larger size peptides than the regular bottom-up. The major challenge is often the selection of the enzyme that will digest proteins into peptides of the appropriate size.

Label-Free Versus Labelled Quantification

Broadly speaking, absolute quantification estimates intracellular protein concentrations on individual samples, and relative quantification compares the measured protein abundances in one sample relative to another. In terms of sample preparation, quantification methods can include stable isotope labels or label-free based.

Adding stable isotope labels significantly reduces experimental bias and improves accuracy, which requires specific but typically straightforward data processing approaches. Relative quantification relies on three main types of techniques in proteomics: metabolic, chemical or enzymatic. The metabolic approach is characterised by the Stable Isotope Labelling with Amino acids in Cell culture (SILAC) method that uses non-radioactive isotopic labelling ([Ong et al., 2002](#)). The chemical methods include isotope-coded affinity tags (ICAT) ([Gygi et al., 1999](#)), isobaric labelling tandem mass tags (TMT) ([Thompson et al., 2003](#)) and isobaric tags for relative and absolute quantification (iTRAQ) ([Ross et al., 2004](#)). The enzymatic approach is illustrated with the $^{16}\text{O}/^{18}\text{O}$ where the enzyme-catalyzed incorporation of oxygen is performed in the C-terminal carboxylic acids of peptides during the digestion procedure ([Yao et al., 2001](#)). In the workflows using of these different methods, samples corresponding to distinct experimental conditions are labelled and combined, and all samples are compared in the same LC-MS analysis of the pooled samples. Labelling is performed on proteins (pre-digestion) or on peptides (post digestion). There is no computational challenge as each mass change caused by labels is known and only mass differences are sought. In the end, label-based methods increase costs (reagents are expensive) and sample preparation time, while limiting the number of different samples that can be compared.

In contrast, in label-free methods different samples are prepared and analysed individually, requiring computational methods to align retention time across multiple samples and to normalise intensity. As ([Bilbao, 2018](#)) is fairly detailed on software available for supporting peptide and protein quantification, this section will only mention image-based analysis. For example, MS1 “2D-images” plotting m/z and retention time (rt) values of peptides have been used and processed in much the same way 2D-gels images are scanned and compared for differential analysis. In this representation, retention time alignment is approached by superimposing 2D (m/z , rt) maps. Solutions to these image processing issues overlapping those raised by 2D-gel analysis are reviewed in ([Dowsey et al., 2010](#)). Furthermore, the technique known as MALDI-imaging mass spectrometry offers yet another label-free technology. A tissue section is coated with matrix and irradiated with a laser. Molecules are then desorbed and ionised according to the MALDI technique. Spectra are acquired from each location (pixel) over the surface of the tissue and 2D ion density images are reconstructed from the spectra ([Seeley and Caprioli, 2008](#)). Image analysis software is listed on the website of the active MALDI-imaging community: <https://ms-imaging.org>.

A comprehensive coverage of quantification should include a mention of targeted proteomics usually opposed to discovery (shotgun) proteomics. Selected reaction monitoring (SRM) has become the MS method of choice to accurately and consistently quantify a selection of proteins across samples. It is typically used as a means of validating the expression of a protein or a proteotypic (i.e., uniquely characterising a protein ([Mallick et al., 2007](#))) peptide. Note that so-called “directed proteomics” is an intermediary strategy that entails using a list of predetermined precursor ions, otherwise called “inclusion list” in order to focus on a particular segment of a global proteome and increase reproducibility. To conclude this section on quantification approaches, [Fig. 4](#) (inspired from [Fig. 1](#) in ([Bensimon et al., 2012](#))) highlights the requirements of the different label-free strategies and the corresponding depth of analysis achieved.

Some Omics Bridging Issues

Needless to say, proteomics as part of the omics landscape is integrated with many other omics. It is virtually impossible to cover all existing options and the following highlights a selection.

Proteogenomics

Genomic sequencing data can be used to improve protein identification through refining the construction of a protein sequence database. Proteomic data can in turn support large scale RNA and DNA sequencing initiatives by providing evidence of coding sequence variants, novel coding transcripts or refined gene boundaries. In fact support to complete genome annotation was suggested

Fig. 4 The various protein identification and quantification strategies and corresponding options at the MS1 level and subsequent MS2 level following precursor ion selection (full red line, required; dashed red line, optional). DDA=Data-Dependent Acquisition (implemented in shotgun proteomics); DIA=Data-Independent Acquisition; “Directed” and “Targeted” are defined in the text. Results are represented in terms of coverage in red volumes to illustrate the depth of analysis.

very early on in proteomics with the prospect of revealing information not accessible in genomics (Küster *et al.*, 2001; Choudhary *et al.*, 2001). But it took longer than expected to design systematic approaches such as Branca *et al.* (2014) and the work that follows to shape the field of proteogenomics. In the meanwhile, isolated attempts led to contribute to plant gene/protein characterisation, e.g., identification of paralogue genes from multigenic families (Delalande *et al.*, 2005) as well as refining bacterial genome annotation, e.g., identification of precise translation start in proteins of *Mycobacterium tuberculosis* (Rison *et al.*, 2007).

Since 2013, efforts in proteogenomics are more structured. For instance it is playing an important role in the Chromosome-Centric Human Proteome Project (C-HPP) developed within the Human Proteome Organisation (HUPO). C-HPP aims at characterising all protein coding genes of the human proteome and the information is collected and centralised in the neXtprot database (Gaudet *et al.*, 2013). Proteogenomics is also gaining attention in bacterial genome sequencing and annotation. Beyond the resolution of ambiguous cases of translations start sites, generic solutions are now available (Omasits *et al.*, 2017) and make a difference in terms of coding sequence annotation in complete genomes.

Another aspect of proteogenomics is shown in the range of software was developed for the identification of sequence variants through building customised databases of protein sequences of known variant peptides. There are basically three options for the search engines used in this context: mass spectra are searched (i) once against a database of mixed of wild-type and variant peptides, (ii) twice against a first database of wild-type and a second database of variant peptides (iii) once against a database of variant peptides. These approaches are benchmarked on two large human and bacterial datasets with two different search engines in Ivanov *et al.* (2017). Despite a preference for the first strategy, results with others are close and possible gaps are influenced by the search database size or the size of the training data set used for validation.

The existence of small open reading frames (less than 300 nucleotides) undetected by gene prediction software (especially in the human and mouse genomes) has been debated prior the finding experimental means to produce evidence. A solution was brought by ribosome profiling coupled to MS-based protein and peptide identification (Koch *et al.*, 2014). This also led to the creation of a database of small ORFs (see “Relevant Websites section”).

Ultimately, proteogenomics has unique information to contribute in the context of other omics. For example, proteogenomic techniques can help assess protein-level expression in viral infections as they alter gene expression and protein production when the virus hijacks cellular processes that allow for self-replication (Ruggles *et al.*, 2017).

Interactomics

The rising of network biology (Barabási and Oltvai, 2004) has significantly modified knowledge representation in molecular biology. In protein science, experimental techniques for studying protein-protein interactions and protein expression in cells and tissues have evolved in parallel for a while and finally met to benefit each other. (Bensimon *et al.*, 2012) provide a very clear account of this mutual influence and resulting integration mostly in the context of systems biology. In fact, proteomics has been used for solving protein-protein interactions in complexes since the publication of the Tandem Affinity Purification (TAP) method (Rigaut *et al.*, 1999). Ten years later, a full pipeline known as ProHits processes raw MS data files to produce fully annotated protein-protein interaction datasets and considered a reference (Liu *et al.*, 2010). The noisy nature of interactomics data led the authors to also release a contaminant database known as the Crapome (<http://www.crapome.org>).

Substantial progress in generating reliable MS-based interactome data is expected to also arise from work that has been and still is invested in detecting protein interactions by cross-link experiments (shortened as XL-MS). The identification of cross-linked peptides from mass spectra and the mapping of identified cross-links in a structural context naturally relies on efficient computational methods, as reviewed in (Yilmaz *et al.*, 2018). Cryo-EM (Electron Microscopy) data was shown to complement XL-MS (Snijder *et al.*, 2017) and such type of “hybrid” MS strategies (i.e., combined with other technologies) is very likely to significantly expand in the years to come.

PTM Detection and Mapping

In this section, two examples of the most frequent PTMs are briefly covered to highlight the productive contribution of bioinformatics in the past decade. Other related issues are discussed later in the open questions.

Phosphoproteomics

O-Phosphorylation, which corresponds to the addition of a phosphate residue on a serine, a threonine or a tyrosine, is a simple modification that plays a central role in signalling processes. A rough estimate of 60% phospho-proteins is given for the content in the human genome (Vlastaridis *et al.*, 2017).

Phosphoproteomics is massively contributing to populating databases such as PhosphoSite (see “Relevant Websites section”). Similar experimental techniques are commonly applied. In particular, metal-based phosphopeptide enrichment strategies methods including immobilized metal affinity chromatography (IMAC) and metal oxide affinity chromatography (MOAC) are prevalent in the field. Phosphopeptide search is often included in database search engines though the remaining challenge remains the positioning of the PTM. Many peptides contain several potential sites and scoring is necessary (Savitski *et al.*, 2011)

As pointed out in Riley and Coon (2016) phosphoproteomics studies tend to focus on O-phosphorylation (serine, threonine, and tyrosine) while alternative N-phosphorylation (lysine, arginine, and histidine) and S-phosphorylation (cysteine) are known to regulate/modulate signalling in bacterial systems, and possibly in eukaryotes as well Kee and Muir (2012). Conventional LC-MS/MS approaches need to be revised to accommodate the specificity of these modifications in higher throughput.

Glycoproteomics

Glycosylation entails the attachment of glycan molecules (oligosaccharides) on proteins. At least 60% of proteins are expected to be glycosylated in mammalian proteomes and many thousands of fully defined glycan structures have been published. Mass spectrometry is the most popular technique to characterise the structure of glycans and glycopeptides; NMR is a common alternative to MS for solving structures with a lesser throughput and higher amounts needed of sample material. A repository of glycan structures each one given a unique identifier was released in an effort to channel the diverse contributions of the glycoscience community (Tiemeyer *et al.*, 2017). In parallel, curated databases are also developed as summarised in Lisacek *et al.* (2017) Fig. 5 illustrates the variety of glycan molecules attached to a specific site of human elastase.

To date, many studies are based on MS1 data and limited to identifying glycopeptides associated with glycan monosaccharide compositions as opposed to fully defined structures, e.g., Rombouts *et al.* (2016). The fragmentation pattern of glycans was analysed and formalised by Domon and Costello (1988). Multiple fragmentation energies may be required to gain enough information on a glycan structure. Then, standard CID fragmentation of glycopeptides tends to reveals mostly losses of glycans via glycosidic bond cleavage, and relatively little peptide bond cleavage. This lack of information means that determining the peptide identity will be difficult.

Technical steps of current glycoproteomics workflows are not evenly mature or optimised. Advanced methods are the result of applicable or transposable proteomics principles while open questions reflect issues specific to the field of glycosciences and still in need to be tackled. Throughput is increasing and in much the same way lessons learnt in proteomics techniques have benefitted those in glycoproteomics, ideas implemented in proteome informatics also deeply influence glycoproteomics data analysis software. For example, data pre-processing approaches are considered operational (handling of raw files, peak picking, spectral matching or deconvolution). In contrast, open questions such as site-specific localisation and profiling of glycosylation, integration of candidate peptide and glycan scores, target-decoy models and FDR calculation still require time to reach a consensus stage. Reviews such as Dallas *et al.* (2013), Hu *et al.* (2016) and Gaunitz *et al.* (2017) provide rich overviews of glycoproteome informatics with detailed analyses of the obstacles to full automation. Interestingly, undertaking the reanalysis of a dataset initially

released as global proteomic and phosphoproteomic analyses led to the identification of a large number of glycopeptides (Hu *et al.*, 2017) thereby demonstrating both the value of reanalysis and the wealth of information hidden in MS data.

Open Questions and Future Directions

Standards and Coverage

To link with the discussion in [Robin \(2018\)](#), the importance of complying with standards in order to support comparability and reproducibility of data is also stressed here. More effort is needed in that direction and not surprisingly new standards are emerging in proteogenomics (proBAM [Menschaert et al., 2018](#)) or in glycoproteomics (MIRAGE [Kolarich et al., 2013](#))

The proBAM format is based on the BAM format originally designed to store alignments of short DNA or RNA reads to a reference genome. The main advantages of proBAM are (i) the connection of proteomics data to a range of bioinformatics tools that process BAM files, (ii) the option to import information about peptide identification to a genome browser, (iii) exchange and re-use of MS-based proteomics data made easier. The production of this format directly stems from recent progress in proteogenomics.

It can be safely assumed that further effort will be invested in developing the necessary tools in particular with the goal of increasing the peptide coverage in protein identification software and mapping the various sources of variations ranging from SNPs (Single Nucleotide Polymorphism) to PTMs.

Method Improvement and Further Integration With Other – Omics

As mentioned throughout this article, technological development plays a key role in the evolution of proteomics. MS-based proteomics methodologies have evolved rapidly over recent years along with a remarkable progress on specialised software. In fact,

proteome informatics has to keep up with constant innovation such as moving from DDA to DIA technologies or tackling the challenges of top down proteomics. Furthermore, new approaches are nowadays used in combination with other omics such as genomics, transcriptomics and metabolomics (see related discussion [Bilbao, 2018](#)).

This increasing throughput and large-scale context is grounded in the big data era and requires robust and efficient MS software as well as advanced MS hardware for comprehensively exploiting the information and generating knowledge. In this sense, progress in instrumentation and analytical methods are expected, and importantly, development of new computational methods to cope with these advances will continue to be an active area of research. An increasing number of available tools including proprietary and open source can be expected.

It should also be noted that both in transcriptomics and proteomics, the unavailability of sequenced or well-annotated genomes and therefore the lack of reference templates limit the interpretation of data. This is particularly acute in plant biology (see for example Special Issue of *Biochimica et Biophysica Acta (BBA) – Proteins and Proteomics* Edited by Hans-Peter Mock Plant Proteomics: a bridge between fundamental processes and crop production, Volume 1864, Issue 8, Pages 881–1060, 2016) and with animals that are not considered as model organisms (see for example [De Almeida et al., 2018](#)). This gap is likely to be filled as genome-sequencing technology advances.

Definite Potential for Elucidating PTM Cross-Talk

As pointed in [Venne et al. \(2014\)](#), PTMs can be mutually exclusive such as the phosphorylation and the O-GlcNAcylation of serine and threonine of signalling proteins presented very early on as the “yin-yang hypothesis” ([Hart et al., 1995](#)) but they can also be cooperative as in the well-studied case of histones ([Schwämmle et al., 2014](#)). However, crosstalk appears to be species-dependent ([Beltrao et al., 2012](#)) making the concept of “PTM code” still difficult to define and circumscribe despite being referred to in many articles (e.g., in relation to chaperones ([Cloutier and Coulombe, 2013](#)) or tubulins ([Janke, 2014](#))). To grasp an understanding of the scenario of protein modifications and better apprehend interplay, work should however not be limited to describing the modified protein “landscape” of a cell or a tissue. As a matter of fact, understanding also means entangling a tight bundle of interactions, which encompasses ascertaining the role, the origin and the purpose of enzymes that carry out PTMs. This task is likely to take a while.

The generalised use of mass spectrometry (MS) following top down, middle down or bottom-up strategies mentioned in Section “Proteomics Workflows”, as well as the refinement of dedicated approaches described in Section “PTM Detection and Mapping”, explain the rather recent accumulation of detected PTMs. The role of PTMs has an obvious bearing on the overall system of interactions. In fact, examples of protein-protein interaction networks integrating PTM knowledge are rare and devoted to mapping data collected in eukaryotes such the yeast methylome ([Erce et al., 2012](#)) or the phospho-tyrosine interaction network in human ([Grossmann et al., 2015](#)). Bioinformatics resources mapping modified protein interactions are still scarce. For example, with a focus on human and mouse data, TOPFind attempts to address this question with the PathFinder tool ([Fortelny et al., 2015](#)) mapping and modelling a protease interaction network.

Conclusion

This overview spans over two decades of bioinformatics development for the reliable identification of proteins in complex mixtures. Many more points and applications could be raised and the reader will find finer details regarding a broad range of topics in cited references. Complexity is unlikely to be reduced in future large-scale studies as hinted in Section “Open Questions and Future Directions” and confirmed for instance by recent effort to launch metaproteomics applications (proteomics of microbiota), which in much the same metagenomics was initiated, cannot be tackled without powerful software ([Muth et al., 2015](#); [Cheng et al., 2017](#)). Proteome informatics can still prosper.

Proteomics Data Representation and Databases

Thibault Robin, University of Geneva, CUI, Carouge, Switzerland

Introduction

Proteomics distinguishes itself from other life sciences by the variety and the complexity of the data generated. Compared to genomics, many biological events such as post-translational modifications, protein isoforms, and protein degradation add challenges to data analysis and interpretation (Altelaar *et al.*, 2012). Furthermore, proteins rarely act independently but rather interact with each other in large intricate, dynamic and plastic networks (Baker, 2012; Altelaar *et al.*, 2012).

In recent years, significant breakthroughs were achieved in proteomics technologies (Altelaar *et al.*, 2012). Mass spectrometry (MS) in particular has emerged as the reference approach for the high-throughput identification of peptides and proteins. This progress was made possible through improvements in sample preparation, instrumentation and computational tools (Altelaar *et al.*, 2012). The widespread adoption of next-generation mass spectrometers by the proteomics community yielded to a massive increase in the amount of data generated, raising concerns about their storage and sharing policies. Despite some initial reluctance, the need for open access data in proteomics is nowadays fully embraced by the community. Although data sharing was introduced a long time ago in other omics fields, it was not effortless in proteomics and required a collective input over the years to convince both researchers and instrument manufacturers (Prince *et al.*, 2004; Verheggen and Martens, 2015; Deutsch *et al.*, 2017).

To meet the demand, a large panel of databases with their respective underlying purpose and content specificities was developed over time. Despite the undeniable biological value provided, the resulting diversity can prove to be troublesome for users who have to grasp the extent of the various data formats for both input and output files. Another consequence of such fragmented information is that long-term database maintenance is not guaranteed. Some databases may be financially impacted when the only source of income lies in research grants and donations. A recent setback was the successive discontinuation of the Peptidome (2011) (Slotta *et al.*, 2009; Csordas *et al.*, 2013) and Tranche (2013) (Smith *et al.*, 2011; Science Signaling, 2013) databases due to the lack of funding, resulting in the partial loss of each dataset (Deutsch *et al.*, 2017). These incidents led the ProteomeXchange consortium to make data sustainability one of its priorities (Deutsch *et al.*, 2017).

This article will describe the proteomics field in regard to the available databases and the data they contain. First, the principal data types are presented along with the corresponding standard formats that were established through the years. Next, the main categories of databases are detailed and illustrated, with representative examples that have the greatest impact on the field today. Then, the ProteomeXchange consortium is detailed to present the significant contribution it brought to the proteomics field. Finally, the prospects of proteomics data and databases are examined.

Data Types and Standard Formats

The data generated in most MS-based proteomics experiments can be divided into two main categories depending on their origin: raw data and processed data. Metadata is a separate though significant category, present throughout the analysis process. Its purpose is to store and track a wide range of technical and biological information, essential to proper data handling and interpretation. Metadata information is especially essential in the proteomics field, since a broad range of approaches and technologies are being used (Table 1).

Raw Data

In its primal form, proteomics raw data is mass spectra. A mass spectrum consists at its core in a collection of mass-to-charge ratios (m/z) plotted against their corresponding intensities (Aebersold and Mann, 2003). Supplementary information is usually provided, such as the precursor ion m/z value and charge along with the retention time when a chromatographic separation step was performed.

Proprietary formats

Mass spectrometers usually produce raw data in the form of proprietary binary files presenting various levels of compression (Martens *et al.*, 2005b). Most of the time, the exact specifications of the format encoding-schemes are not publicly available. Proprietary binary files cannot consequently be accessed by users without software supplied by the instrument vendor. Likewise, third-party software, such as MSConvert from the ProteoWizard suite (Kessner *et al.*, 2008), will require the implementation of specific proprietary libraries to decode the information contained in the data files. The data formats also change drastically from one vendor to another, or even sometimes between instruments, raising important standardization concerns. Despite all the restrictions, proprietary formats contain the greatest amount of information and present overall good performances when being processed by compatible software.

Table 1 Summary of the main open data formats in the proteomics field

Name	Supported Data	Organization	URL
mzData	Raw mass spectra	Proteomics Standards Initiative, Human Proteome Organization	http://www.psdev.info/mzdata
mzXML	Raw mass spectra	Seattle Proteome Center, Institute for Systems Biology	http://tools.proteomecenter.org/wiki/index.php?title=Formats:mzXML

mz5	Raw mass spectra	Proteomics Center, Boston Children's Hospital	http://software.steenlab.org/mz5
TraML	SRM transition lists	Proteomics Standards Initiative, Human Proteome Organization	http://www.psdev.info/traml
mzIdentML	Identification data	Proteomics Standards Initiative, Human Proteome Organization	http://www.psdev.info/mzidentml
mzQuantML	Quantification data	Proteomics Standards Initiative, Human Proteome Organization	http://www.psdev.info/mzquantml
pepXML	Identification and quantification data	Seattle Proteome Center, Institute for Systems Biology	http://tools.proteomecenter.org/wiki/index.php?title=Formats:pepXML
protXML	Identification and quantification data	Seattle Proteome Center, Institute for Systems Biology	http://tools.proteomecenter.org/wiki/index.php?title=Formats:protXML
mzTab	Identification and quantification data	Proteomics Standards Initiative, Human Proteome Organization	http://www.psdev.info/mztab

Peak list formats

The limitations of the proprietary formats favored the common practice of extracting the mass spectra from the binary files as peak lists stored in text files at the cost of an overall reduced amount of information. In addition to the almost complete loss of metadata information, the mass spectra usually go through denoising, deisotoping, centroiding and charge deconvolution steps during the format conversion (Martens *et al.*, 2005b). The resulting peak list files are therefore significantly more compact while becoming easily manageable for users. The lack of metadata represents the main shortcoming of this format, making it poorly adapted to data storing and sharing.

Many peak list formats were developed through the years, such as the Mascot generic format (MGF), the Micromass peak lists (PKL) and the SEQUEST files (DTA). Despite slight variations in the amount of information they contain, these formats are easily inter-convertible without significant data loss using publicly available software (Martens *et al.*, 2005b).

mzData and mzXML formats

In order to determine a middle solution between proprietary binary files and basic peak lists, new open data formats were proposed at the beginning of the 2000s owing to the expansion of XML (Extensible Markup Language) in bioinformatics. For several years, the mzData (HUPO-PSI, 2006) and mzXML (Pedrioli *et al.*, 2004) formats used to be the most common open data formats to store and share raw data information (Martens *et al.*, 2011). Although sharing the same XML architecture, the two formats mainly differed in regard to their ontology policies (Martens *et al.*, 2011).

On the one hand, the mzData format was developed by the HUPO Proteomics Standards Initiative (PSI) as an open format standard to share and archive data. Its metadata annotation was based on a controlled vocabulary that could be regularly updated (Martens *et al.*, 2011). On the other hand, the mzXML format was developed at the Institute for Systems Biology (ISB) as an open data format accompanied by a suite of tools (Pedrioli *et al.*, 2004). Its metadata annotation was based on a fixed schema that required modification along with the corresponding software to incorporate new annotations (Martens *et al.*, 2011). Although nowadays deprecated, the mzData and mzXML formats are still compatible with most current software and are being used at a smaller scale by the proteomics community.

mzML format

With the purpose of format unification, the mzML format was developed as part of a collective effort under the guidance of the HUPO-PSI to replace both the mzData and mzXML formats (Martens *et al.*, 2011). The coexistence of two open formats having similar functionality was perceived at the time as confusing for users. The goal was then to design a unique XML-based format supporting all past features while providing a consensus way to encode the information (Martens *et al.*, 2011). In addition to instrument support improvement, the mzML format features notably metadata annotation following a flexible controlled vocabulary that allows the inclusion of custom new terms by users without requiring the modification of the XML schema (Martens *et al.*, 2011). The mzML format quickly became compatible with most tools available in proteomics, strengthening its format unification goal.

mz5 format

More recently, the mz5 open data format was developed at the Proteomics Center of the Boston Children's Hospital with the aim of providing a more speedy and storage efficient alternative to mzML while preserving the same ontology (Wilhelm *et al.*, 2012).

Distinguishing itself from its predecessors, the mz5 format is designed based on the Hierarchical Data Format (HDF5) instead of the traditional XML architecture. Despite the partial base-64 encoding being used in mzML, XML was designed to remain easily manipulable by users and consequently struggles to handle massive data files. With data benchmarks, the mz5 format was shown to increase 3–4 times read and write performances while halving data file size in comparison to its XML-based counterparts (Wilhelm *et al.*, 2012). Despite its obvious benefits, the low amount of compatible software prevented the widespread adoption of the mz5 format by the proteomics community.

Processed Data

In most high-throughput proteomics experiments, peptide and protein identification is achieved through the database search approach (Nesvizhskii, 2006). In this method, the experimental spectra are aligned against theoretical spectra inferred from the fragmentation patterns of the peptides contained in a reference protein sequence database. The tools performing the search, referred to as search engines, additionally provide numerous statistical scores assessing the quality of the resulting peptide-spectrum matches (PSMs), allowing to rank the peptides matching a given experimental spectrum (Nesvizhskii, 2006). In a further step, the identified peptides are used to determine the proteins from which they originated. Protein inference can however prove to be challenging, especially in eukaryote species, because peptides can belong to several distinct proteins and multiple protein isoforms may coexist (Nesvizhskii, 2005). The notion of proteotypic peptide was then introduced to single out those peptides that are unique to a protein.

Protein identification is the main task in most MS data processing workflows. Nonetheless, protein quantification is also frequently performed. Quantification experiments usually have the aim of comparing protein expression across multiple samples prepared in distinct conditions, although absolute quantification of proteins can also be achieved. Two mutually exclusive strategies have been established through time for quantification in proteomics: stable isotope labeling and label-free quantification (Bantscheff *et al.*, 2007). In stable isotope labeling approaches such as SILAC (Ong *et al.*, 2002), a mass tag is inserted in proteins through a wide range of experimental protocols. The induced mass shift between the light and heavy forms of peptides is detectable by mass spectrometers, leading to the relative quantification of the proteins of interest through the comparison of the signal intensities (Bantscheff *et al.*, 2007). The label-free approaches expanded more recently with the emergence of more accurate instruments. Being usually based either on spectral counting or on precursor ion intensity, label-free approaches do not include any isotope-tagging step and consequently reduce the sample preparation complexity (Bantscheff *et al.*, 2007).

PepXML and protXML formats

The pepXML and protXML formats (Keller *et al.*, 2005) were originally developed with the purpose of improving and facilitating data transfer between the various tools being part of the Trans-Proteomic Pipeline (TPP) (Keller *et al.*, 2005). The pepXML format stores and shares peptide identification and quantification data while the protXML format focuses solely on the corresponding protein data (Deutsch *et al.*, 2015). Some search engines can directly output their results into files in the pepXML format to be further processed by the TPP. Converter tools are also available in the TPP for the other formats. Although the pepXML and protXML formats were not defined with the underlying aim of becoming official standard formats, many tools outside the TPP adopted them over the years (Deutsch *et al.*, 2015).

mzIdentML and mzQuantML formats

To provide a reliable open standard format for the distribution of peptide and protein identification data, mzIdentML was developed by the HUPO-PSI alongside with a suite of converters for most open and proprietary formats available (Jones *et al.*, 2012). As in the case of pepXML and protXML, search engines that evolve over the years offer the option to export directly their results in the mzIdentML format (Jones *et al.*, 2012).

Based on the success of mzIdentML, the mzQuantML format was launched shortly thereafter under the direction of the HUPO-PSI as a quantitative-focused counterpart (Walzer *et al.*, 2013). It was developed to answer the pressing need for a standard format in quantitative proteomics, especially since the techniques and approaches may diverge significantly between individual experiments (Walzer *et al.*, 2013). The mzQuantML format notably features the ability to cross-reference other XML-based open formats such as mzML and mzIdentML. These cross-links help to keep track of the numerous data and metadata produced throughout the analysis workflow (Walzer *et al.*, 2013). Both formats are based on the same controlled vocabulary that was introduced by the HUPO-PSI for mzML (Jones *et al.*, 2012; Walzer *et al.*, 2013), thus providing a robust yet flexible way to annotate metadata information.

mzTab format

The mzTab format was recently launched by the HUPO-PSI as a complement to both the mzIdentML and mzQuantML formats (Griss *et al.*, 2014). The underlying purpose was to design a simple tabular format summarizing identification and quantification data from proteomics and metabolomics experiments. As the strength of the format resides in the easy report of experimental results, it usually contains an overall lower amount of information compared to most XML-based formats (Griss *et al.*, 2014). Files in the mzTab format do not require specific parsing software since no special encoding is involved, which significantly simplifies their handling by users.

TraML format

Through the years, more specialized open formats also made their apparition in the proteomics field. The TraML (Deutsch *et al.*, 2012) standard format developed by the HUPO-PSI is such an example, capturing solely the transition lists resulting from selected reaction monitoring (SRM) experiments. In SRM approaches, a transition represents the pair of m/z values of the targeted peptide precursor ion and of one of its corresponding fragment ions. TraML is designed around the same principles that were established for the mzML and mzIdentML formats, using an XML-based architecture along with a controlled vocabulary encoding the metadata information (Deutsch *et al.*, 2012).

Databases and Repositories

Databases in the proteomics field differ strongly in terms of both their purpose and the data they contain. While some solely serve as repositories for the dissemination of experimental datasets, others have been developed with more advanced functions such as sequence annotation or targeted research goals.

Proteomics databases and repositories are still under substantial development in comparison to other life science fields. This delay can partially be explained by the initial skepticism of a part of the proteomics community in regard to sharing publicly experimental data due to data submission imposed by publishers. One of the common concerns was the possible third-party reanalysis of datasets prior to result release in a publication of the original submitter. To address this issue, most databases feature nowadays the ability to keep dataset submission private for the duration of the reviewing process (Vizcaíno *et al.*, 2014).

Needless to say, UniProt (The UniProt Consortium, 2017) remains arguably the most popular and internationally renowned resource for proteins, playing a central role in the proteomics database landscape as the ever-present reference for protein annotation. As UniProt is however a knowledge database that contains almost to no MS data, it will not be presented in details here (Table 2). Likewise, the species-specific resources will also not be discussed in this article.

GPMdb

The Global Proteome Machine database (Craig *et al.*, 2004) (GPMdb) was initially designed by Beavis Informatics for the purpose of storing the reprocessed data produced by the GPM data analysis servers. In this automated pipeline, the MS raw data submitted by users or contained in other databases are reanalyzed using the online version of the X!Tandem (Craig and Beavis, 2004) search engine. The input files submitted to the GPMdb have to be formatted either as peak list (DTA, PKL or MGF) or in a compatible open standard format (mzXML or mzData). In addition to a large panel of search parameters, the users can choose prior to the database search if they authorize the inclusion of the dataset to the GPMdb. With the accumulation of a large amount of data over the years, the GPMdb has diversified its functions and is today commonly used by researchers to compile spectral libraries and develop related search tools. This notably led to the inception of the X!Hunter (Craig *et al.*, 2006) online search engine, which can perform the search of experimental mass spectra against consensus spectral libraries built from the GPMdb.

PeptideAtlas

The PeptideAtlas database (Desiere *et al.*, 2006) was originally developed in 2004 at the Institute for Systems Biology (ISB) as a resource providing genome annotations from the automatic reprocessing of MS raw data by the TPP pipeline. PeptideAtlas presents the peculiarity of being composed of distinct builds according to the organism or tissue of interest (Deutsch *et al.*, 2008). Another noteworthy feature of PeptideAtlas consists in the computation of an observability score for each proteotypic peptide represented in the database (Deutsch *et al.*, 2008). This offers the option of determining the peptides that are the most likely to be detected in a MS experiment for a given protein. As in the case of the GPMdb, the PeptideAtlas database surpassed its initial annotation purpose and is nowadays frequently used as a research database for the compilation of spectral libraries.

Table 2 Summary of the main public databases and repositories in the proteomics field

Name	Supported Data	Organization	URL
PRIDE Archive	Raw and processed data	European Molecular Biology Laboratory, European Bioinformatics Institute	https://www.ebi.ac.uk/pride/archive
MassIVE	Raw and processed data	Center for Computational Mass Spectrometry, University of California San Diego	https://massive.ucsd.edu
jPOSTrepo	Raw and processed data	National Bioscience Data Center, Japan Science and Technology Agency	http://jpostdb.org
PASSEL	SRM raw data	Seattle Proteome Center, Institute for Systems Biology	http://www.peptideatlas.org/passel
GPMdb	Processed data	Beavis Informatics	http://gpmdb.thegpm.org
PeptideAtlas	Processed data	Seattle Proteome Center, Institute for Systems Biology	http://www.peptideatlas.org

PASSEL

The PeptideAtlas SRM Experiment Library (PASSEL) was developed in the framework of the PeptideAtlas project (Farrah *et al.*, 2012). It was designed as a receiving repository for data produced in SRM experiments. In addition, the raw data submitted to PASSEL are automatically reprocessed by specific tools such as mQuest from the mProphet suite (Reiter *et al.*, 2011). The results of this workflow are stored in a separate database that can be accessed through the PASSEL web interface. Among all the obtained transitions, those considered to be the best based on quality metrics are included in the SRMATlas database (Picotti *et al.*, 2008).

PRIDE/PRIDE Archive

The Proteomics Identifications (PRIDE) database (Martens *et al.*, 2005a) was established in 2004 at the European Bioinformatics Institute (EBI) as a structured repository designed to propagate experimental proteomics data. The underlying intent was to provide a resource that would keep the submitted data intact, preserving it from any kind of control or alteration. PRIDE contains both the raw MS data and the resulting peptide and protein identifications, along with the corresponding biological and experimental metadata (Martens *et al.*, 2005a). As of 2014, the PRIDE database was entirely redesigned and replaced by PRIDE Archive (Vizcaíno *et al.*, 2016). The most significant structural changes brought by PRIDE Archive lie in a new data storage architecture and submission system along with a reworked web interface (Vizcaíno *et al.*, 2016).

The Peptidome database (Slotta *et al.*, 2009) was a public data repository developed in 2009 at the National Center for Biotechnology Information (NCBI) that aimed to allow the exchange of experimental proteomics data. Peptidome was thus closely related to PRIDE in terms of both its aim and features. After the discontinuation of Peptidome in 2011 due to lack of funds, a coordinated effort of both teams led to transfer most of its content to the PRIDE repository (Csordas *et al.*, 2013).

MassIVE

The Mass spectrometry Interactive Virtual Environment (MassIVE) repository was developed at the Center for Computational Mass Spectrometry (CCMS) as a public data repository for datasets produced in MS-based proteomics experiments. Compared to other repositories, MassIVE aims to enhance the interactivity of its content. A noteworthy feature is the ability to add comments and reanalyzes for a given submitted dataset. MassIVE also provides the possibility to directly reprocess the raw data that were submitted using several online workflows.

Tranche (Smith *et al.*, 2011) was a public data repository developed in 2005 as part of the Proteome Commons network that aimed to transfer proteomics raw datasets at a large scale. Since the repository had to handle a high data traffic in relation with the large file size, a special effort was made in the design of an efficient peer-to-peer infrastructure coupled with a reliable client-server architecture (Smith *et al.*, 2011). After the funding shortfall that led to the discontinuation of Proteome Commons and Tranche in 2013 (Science Signaling, 2013), as many data sets as possible were recovered and transferred to MassIVE (Deutsch *et al.*, 2017).

jPOST

The Japan Proteome Standard (jPOST) is an emerging resource that ultimately aims to provide both a repository and a database for the worldwide proteomics community. On the one hand, the jPOST repository (jPOSTrepo) (Okuda *et al.*, 2017) was launched at the National Bioscience Data Center (NBDC) in 2015 as a platform for the global exchange of datasets produced in MS-based proteomics experiments. The underlying aim was to offer an alternative for the Asia and Oceania regions to the existing proteomics repositories. Indeed, most public MS data resources are either hosted in Europe (PRIDE Archive) or in the United States (PASSEL, MassIVE). This can prove to be problematic in terms of data transfer speed for researchers who agree to share their experimental datasets but are located far away from these regions. A special effort was thus additionally undertaken to deploy an efficient file upload system, further facilitating data exchange (Okuda *et al.*, 2017).

On the other hand, the jPOST database (jPOSTdb) is still under development and has not been made publicly available yet. Eventually, jPOSTdb will include the automatic reprocessing of the MS raw data submitted to jPOSTrepo through a customized workflow using a combination of several search engines.

ProteomeXchange Consortium

The ProteomeXchange (PX) consortium (Vizcaíno *et al.*, 2014) was originally formed in 2006 and officially launched in 2011 as a collective effort to coordinate data exchange and submission between MS-based proteomics databases and repositories. Since the partner resources had been developed independently at distinct research institutions, it resulted in limited coordination in regard to their respective data submission guidelines and policies (Vizcaíno *et al.*, 2014). This proved to be troublesome for researchers willing to share their experimental data, struggling to determine where and in which form datasets should be submitted. Likewise, data comparison through the use of several sources could turn out to be challenging. The purpose of the PX consortium was to remove these obstacles by providing a regulated infrastructure and framework (Vizcaíno *et al.*, 2014). Such an initiative had already been successfully implemented in other omics fields, as for instance with the development in genomics of the International Nucleotide Sequence Database Collaboration (INSDC) (Cochrane *et al.*, 2016) to regulate the dissemination of DNA sequencing data.

In its first inception, the PX consortium had only two core members: PRIDE and PeptideAtlas (along with its PASSEL resource) (Vizcaíno *et al.*, 2014). PRIDE was used at the time as the unique entry point for data produced in shotgun proteomics experiments, whereas SRM data were redirected to PASSEL. In the pursuit of its unification role, more receiving repositories progressively joined the PX consortium in recent years. This led notably to the inclusion of the MassIVE repository in 2014, followed shortly by the addition of jPOST in 2016 (Deutsch *et al.*, 2017). More emerging resources are also expected to become members of the PX consortium in the future, further improving the state of data sharing in the proteomics field.

Data submission in the PX consortium can be subdivided in two distinct workflows: complete and partial (Deutsch *et al.*, 2017). In a complete submission, the format of all the submitted files can be recognized and parsed by the receiving repository. It is the recommended submission process in most cases, as it allows searching directly through the results with precise queries. A partial submission contains files that are in a non-compatible format, thus preventing the receiving repository to read them. As with the complete submissions, the files can however still be searched using the associated submission metadata. Despite its limitations, the partial submission process remains essential to support the inclusion of datasets coming from a broad range of proteomics experiments, including marginal or emerging techniques (Deutsch *et al.*, 2017).

Both complete and partial workflows require the submission of the raw data, the processed data and the corresponding biological and technical metadata information. The latter is encoded in an XML format that was specifically developed for the PX consortium (PX XML) (Vizcaíno *et al.*, 2014). After submission, each dataset is assigned a unique PX identifier. A receiving repository specific identifier is additionally assigned, except for PRIDE (Deutsch *et al.*, 2017). If a dataset was submitted as complete, a digital object identifier (DOI) is also created to allow proper referencing in case of reanalysis in another project (Vizcaíno *et al.*, 2014). Since data reuse is also one of the main focuses of the PX consortium, distinct identifiers are specifically generated to track reprocessed datasets and store corresponding results (Deutsch *et al.*, 2017).

The publicly available datasets stored in the resources of the PX consortium are accessed and queried through the ProteomeCentral online portal, which was deployed from the first version. ProteomeCentral notably features the ability to filter the datasets using metadata keywords, which can be for instance used to retrieve solely the set of results matching a given organism, tissue or MS instrument (Deutsch *et al.*, 2017). A RSS feed was also set up to push updates about new publicly available datasets that are released in the PX consortium, providing links to both the ProteomeCentral entry and the corresponding PX XML file storing the submission metadata (Vizcaíno *et al.*, 2014).

Despite the essential contribution brought by PX consortium to the proteomics field, there is still room for improvement. Some work remains for example to be done regarding the compatibility of complete submission with data produced by increasingly popular experimental approaches, such as the data independent acquisition, top-down proteomics or MS-based imaging techniques (Deutsch *et al.*, 2017). The MassIVE repository already started this process by becoming compatible with some DIA-based workflows (Deutsch *et al.*, 2017). The PX consortium is arguably the most impactful initiative that occurred in recent years for databases and repositories in proteomics, bringing together the different resources in the field and standardizing data submission, processing and dissemination.

Conclusion and Prospects

The successful outcome of collective efforts such as the ProteomeXchange initiative has significantly boosted data sharing in the proteomics field. An obvious consequence is the increasing number of journal editors who nowadays mandate the deposition of the original raw datasets to enhance the publication of scientific articles and allow for evidence checks. Further into the future, more integration of the different omics fields is to be expected. Progress has already been made in this direction with the recent development of the Omics Discovery Index (OmicsDI) portal (Perez-Riverol *et al.*, 2016). OmicsDI aims to provide an online platform for the dissemination and access of datasets from genomics, transcriptomics, metabolomics and proteomics resources. Tighter collaboration between proteomics and metabolomics is also likely, based in particular on the fact that both fields rely predominantly on MS-based approaches and techniques to produce their data. Some open standard formats such as mzTab have already started to become compatible with metabolomics workflows.

Biographical Sketch

Thibault Robin is a Ph.D. student in bioinformatics at the Proteome Informatics Group (PIG) of the Swiss Institute of Bioinformatics (SIB) affiliated with the University of Geneva. After obtaining a Bachelor degree in biology in 2013, he developed a strong interest for informatics and programming. This led to his graduation with a Master degree in bioinformatics in 2015. He is currently working on the development of new proteomics tools, focusing in particular on post-translational modifications and sequence variants.

Proteomics Mass Spectrometry Data Analysis Tools

Aivett Bilbao, Pacific Northwest National Laboratory, Richland, WA, United States

Introduction

The overall purpose of proteomics is the large-scale study of genes and cellular functions at the phenotype level. Information on protein abundances, their variations and modifications, and their interacting networks are critical for understanding complex biological processes, which in turn, are useful to accomplish scientific developments such as effective diagnostic techniques and disease treatments (Aebersold and Mann, 2016; Szabo and Janaky, 2015). The ability to quickly and consistently analyze the large amounts of experimental data produced in proteomics research relies on software advances (Nesvizhskii, 2010; Yates, 2015). Bioinformatics have emerged as a crucial contributor with the development of novel algorithms, the connection of various tools into complex pipelines, as well as the deposition and dissemination of both software and data. In particular, the prominence of open source software and public data in reproducible research has been recently highlighted in several publications (Deutsch *et al.*, 2017; Jiménez *et al.*, 2017; Martens and Vizcaíno, 2017; da Veiga Leprevost *et al.*, 2017; Wilkinson *et al.*, 2016).

As a specialized section of “Proteome Informatics” (Lisacek), this article provides an up-to-date and focused literature review of the software for MS-based proteomics. In particular, freely available and open source tools are cited and discussed, providing a solid starting point with relevant notions for both non-specialized end-users and bioinformaticians.

Since understanding of the data structure is critical to comprehend the processing software methods and obtaining accurate results, the first section summarizes the MS data acquisition process and spectral types currently employed in discovery or untargeted proteomics. Next, the general workflows are discussed and the community efforts to facilitate reproducible research are highlighted. In the remaining sections, algorithmic concepts related to identification, statistical assessment of error rates and quantification tools are compared with an emphasis on the most popular free and open source tools. The review concludes with a discussion of pertinent guidelines and future directions in the field.

Understanding Mass Spectrometry Data From Proteomics Analyses

Discovery of the proteins present in a sample is typically achieved by liquid-chromatography (LC) coupled to mass spectrometry (MS). In the so-called shotgun or bottom-up approach, complex protein samples are digested into peptides. The most popular enzyme used for protein digestion is trypsin, which leads to peptides with C-terminally protonated amino acids, providing an advantage in subsequent MS-based peptide sequencing (Aebersold and Mann, 2016; Aebersold, 2003). As peptides elute from the LC column, they are ionized by electrospray (ESI) and subsequent ions are analyzed by the mass spectrometer. In the traditional data-dependent acquisition (DDA) mode, the MS instrument is operated to maximize the number of selected and fragmented peptides, as they elute from the LC column. Within each DDA cycle, ion signals are recorded in a MS1 or survey scan (precursor ion signals) and the top-*n* most abundant ions are then selected and serially isolated for fragmentation (MS/MS, MS2 or tandem MS) to generate structural information. Alternatively, the mass spectrometer can be operated in data-independent acquisition mode (DIA), where all ions from peptides eluting during LC-MS analysis are fragmented and analyzed in parallel, regardless of their intensities. The advantages and disadvantages as well as specific flavors of DIA with a focus on processing software strategies are discussed in Bilbao *et al.* (2015a).

The different type of generated spectra is illustrated in Fig. 1. Data analysis tools pertinent for each spectral type are discussed in the following sections.

The Data Processing Workflow in MS-Based Proteomics

A wide range of informatics methods comprises signal processing of raw MS data, identification and quantification approaches for protein characterization, assessment and control of error rates, as well as application of statistical and machine learning techniques to unravel relevant protein targets and interacting networks in complex processes. Development and software implementation of algorithms for every step is a laborious process that requires substantial amounts of time and effort. As a result, the complete proteomics data analysis is a composite procedure involving several specialized tasks which are interconnected as a software workflow or pipeline (Fig. 2). These specialized tools have been developed and improved over the years in a stepwise fashion (Noble and MacCoss, 2012), which has greatly promoted the field but also raised major challenges when moving from single and individual tools to complex and integrated workflows: software availability and reproducible results. The challenges have historically rendered bioinformatics as the most difficult area in MS-based proteomics research (Aebersold, 2009). Multiple tools normally require substantial effort and informatics skills for correct installation and configuration (da Veiga

Fig. 1 Sample analysis and mass spectrometry data in discovery proteomics. Following sample preparation and enzymatic digestion, complex peptide mixtures are separated by LC and peptide ions are generated by ESI. The mass spectrometer analyses and detects the peptide ions as they elute. Files with raw MS data are generated from each sample. A file usually contains precursor (MS1) and fragment (MS2) ion spectra. Consecutive spectra in the analysis run are represented by dashed lines. A first representation of the data is the MS1 total ion chromatogram (TIC, blue trace), which is the sum of all ions detected at each time point or spectrum. Examples of MS2 spectra acquired for a specific time range are shown, depending on the MS operation mode used in the analysis run. In DDA mode, the mass spectrometer generates MS2 spectra after isolation and fragmentation of selected precursor ions. The top-2 most intense ions (red and blue LC-MS peaks) are selected to collect individual MS2 spectra at discrete time points and the low abundance one (green LC-MS peak) is undetected. Ions can be selected or not at any time point across the LC peak. In DIA mode, the mass spectrometer generates MS2 spectra of multiple co-eluting ions which are fragmented all together. Continuous fragment ion traces are recorded in convoluted or multiplexed MS2 spectra. Multiple LC-MS/MS peaks from the 3 fragmented peptide ions are detected, including the low abundance one (green LC-MS/MS peaks).

Fig. 2 General proteomics data processing workflow. Processing steps are shown as interconnected boxes. Above and below each step, available logos from example tools and visual representations are included, respectively. Some tools include a graphical user interface (GUI) or only command-line access. In the first step, raw MS data in proprietary formats from different instrument vendors are typically converted to open data formats. Pre-processing can involve centroid data generation, where multiple measurements per peak (black traces) are reduced to single centroid peaks (blue sticks). Next, identification followed by assessment and control of error rates are performed. Quantification information of confident identifications across multiple samples are used as input for downstream analyses and biological interpretations. For label-free data, quantification include a multi-sample alignment step.

Leprevost *et al.*, 2017), lack appropriate documentation and have poor or none graphical user interface (GUI) (Cappadona *et al.*, 2012).

Fortunately, software availability challenges are being recently addressed with the incorporation of advances in software engineering and the contributions from open-source and community-driven efforts.

The BioContainers framework (da Veiga Leprevost *et al.*, 2017) (see Relevant Websites Section) adopted container based technologies such as Docker or rkt to provide complete pipelines as easily installable, deployable and executable packages.

The ELIXIR Tools and Data Services Registry (see Relevant Websites Section) (Ison *et al.*, 2016), is a catalogue of bioinformatics software and resources with extensive metadata descriptions.

A useful list of free software for analysis of mass spectrometry data can be found in <http://www.ms-utils.org>.

Other efforts to provide well-documented software parameters and dependencies include workflow systems such as KNIME (Berthold *et al.*, 2009) and the Galaxy platform (Afgan *et al.*, 2016). Examples for proteomics are the OpenMS 2 tools (Aiche *et al.*, 2015) delivered as KNIME (see Relevant Websites Section), and proteomics workflows in Galaxy (see Relevant Websites Section) for OpenMS, the Trans-Proteomic Pipeline (TPP) and MaxQuant.

The other component for reproducible research, besides the software, is the data itself. Along the same lines of efforts, current requirements from scientific journals and funding agencies have promoted a change of mentality: public data sharing is a common acceptance as good scientific practice in the proteomics field, as embraced earlier in genomics and transcriptomics (Martens and Vizcaíno, 2017).

The set of principles referred to as the FAIR Data Principles that requires data to be Findable, Accessible, Interoperable, and Reusable in the long-term has been recently published as a guideline to support and enhance the reusability in contemporary e-Science (Wilkinson *et al.*, 2016).

The ProteomeXchange (PX) Consortium (see Relevant Websites Section) standardizes submission and dissemination of mass spectrometry proteomics data worldwide (Deutsch *et al.*, 2017).

Recent and detailed information about proteomics data representation and databases can be found in the complementing article “Proteomics data representation and databases”.

As a remarkable outcome of the mentioned efforts, the majority of the software tools and related data discussed in the following sections are freely available to the community. All readers, from end-users to software developers, are invited to explore and download content from the cited resources for gaining a better understanding of the tools, familiarize with the data and optimizing parameters for better results.

It is important to note that there is a myriad of tools and that new ones regularly come out. Evaluating a tool can be time-consuming and demands patience. It is common to find many tools stating to have the needed functionality. However, a deep examination is often required to determine whether the statements are true or whether the tool fits the specific user needs. It is recommended to select a tool taking into account the input and output file formats, available documentation, tutorials and test data, and related publications including application studies. It is equally important to check if the tool is actively maintained and updated, which informatics skills are needed and how scalable it is. Regarding the later point, a few files should be tried first to become familiar with the tool, adjust parameters and evaluate results, and then more files could be processed according to a given study to evaluate if the tool is likely or not to handle all the data.

Preprocessing MS Data

After the mass spectra acquisition, the first step in the informatics pipeline involves several preprocessing methods. Since current MS instruments acquire high resolution data in profile mode, centroid data is computationally generated either during or post-acquisition (Fig. 2, conversion and pre-processing). Preprocessing methods include mass calibration, noise removal, peak picking and grouping of peaks into isotopic profiles with deconvolution and charge-state determination. Preprocessing allows significant data reduction and enhancement for further analysis. Format of raw MS files depends on the instrument vendor, as each of the major vendors uses its own proprietary binary format and continuously update it to support new features of their instruments. Therefore, open formats such as mzXML (Pedrioli *et al.*, 2004) and mzML (Martens *et al.*, 2011) have been created by the proteomics community and developers of analysis software to enable the exchange of data between tools. An overview of the most common file formats used in MS-based proteomics can be found in Deutsch (2012).

Raw MS data processing can be performed using proprietary software provided by the instrument vendors, which may produce better results because methods are customized to pair the characteristics of the data generated by the specific instrument. Alternatively, raw MS data can be parsed from the vendor format to open file formats – with or without preprocessing – to continue the processing pipeline using other software tools. The freely available ProteoWizard toolkit (Chambers *et al.*, 2012) provides software for converting proprietary files from most vendors to open file formats and includes several preprocessing algorithms both open source from the community and non-open source from the vendors. Other software platforms including preprocessing tools are OpenMS (Röst *et al.*, 2016; Sturm *et al.*, 2008), MaxQuant (Cox and Mann, 2008; Tyanova *et al.*, 2016) and MzJava (Horlacher *et al.*, 2015b).

A special case is the Skyline software tool for quantification (MacLean *et al.*, 2010; Pino *et al.*, 2017), where MS data from many instrument vendor formats can be imported directly, i.e., a conversion to open file formats is usually not required.

Identification by Tandem Mass Spectrometry

The fragmentation pattern encoded by a tandem or MS/MS spectrum yield identification of the corresponding peptide sequence. The so-called search engines (Fig. 2, identification) annotate the MS/MS spectra with peptide sequences using various algorithms and scoring strategies (Nesvizhskii, 2010). Peptide identification strategies, discussed in detail in (Lisacek), can be roughly classified into four categories: database search, spectral library search, de-novo sequencing and hybrid approaches such as sequence tag-assisted database search.

SEQUEST (Eng *et al.*, 1994) and MASCOT (Perkins *et al.*, 1999) proprietary database search engines have been traditionally and predominantly used. Nowadays, open source tools are becoming more popular, with increased robustness, usability and flexibility for customization or addition of new features. For instance, Comet is an academic version of SEQUEST. Table 1 summarizes examples of free and/or open source peptide identification software currently available.

As Table 1 shows, most of the identification tools do not have a GUI. Andromeda is available as standalone or integrated into MaxQuant. The SearchGUI (Vaudel *et al.*, 2011) (see Relevant Websites Section) provides an open source, user friendly framework to operate multiple command line search engines.

In terms of scoring, several properties can be taken into account to measure the similarity between an experimental spectrum and a reference. The precursor mass is mainly used to restrict the search space. However, the mass differences for both the matching fragments and precursor can be considered into the scoring. Other properties include the number and intensities of the experimental peaks, number of complementary ions, number of missed cleavages and number (and types) of modifications.

A great variety of scoring strategies have been proposed for peptide identification. Broadly speaking, they can be divided into heuristic and probabilistic schemes. Heuristic methods typically combine a set of scoring properties in a practical form reflecting expert knowledge. A product or a linear function are simple examples of how these properties can be combined into a scoring function. Probabilistic schemes compute the probability that a given sequence is the origin of the spectrum.

With the introduction of machine learning, algorithms that can automatically learn from training data have been applied to many fields, including proteomics. Specifically, MSGF+ is able to automatically derive scoring parameters from annotated spectra. More recently, DeepNovo implements a deep neural network model for de novo peptide sequencing.

Finally, the actual software implementation of the algorithm makes a great difference in terms of computing resources required by the tool. By using a fragment-ion indexing method, MSFragger enables a significant improvement in speed over most existing proteome database search tools.

Post-Translational Modifications

Post-translational modifications (PTMs) are alteration of proteins during or after protein biosynthesis, resulting in changes of the protein physicochemical properties which modulate and regulate cellular functions. Abnormal PTM abundances are involved in disease states.

^aAn alternative version is available through TPP GUI.

By identifying the occurrence of regular mass shifts corresponding to the addition or removal of chemical groups of known masses in a peptide MS/MS spectrum, it is possible to identify a PTM and its position on the peptide sequence. When specified in the search parameters, search engines can consider relevant PTMs, such as phosphorylation. However, this number is usually limited because the search space is substantially expanded. Consequently, an important fraction of MS/MS spectra usually remains unidentified, mainly due to the diversity of PTMs and other chemical modifications that are unaccounted. An attractive exception is the automatic PTMs detection algorithm in the proprietary search engine ProteinPilot (Shilov *et al.*, 2007), where modifications, substitutions, and cleavage events are modeled with probabilities rather than by discrete user-controlled settings. This alleviates the user with the tedious task of optimizing parameters.

A range of tools have been developed to perform the so-called “open modification search”, i.e., searching with no a priori PTM information (Ahrné *et al.*, 2010). Approaches aiming to automatically discover unexpected modifications in high throughput proteome data include: MODa (Na *et al.*, 2012), MzMod (Horlacher *et al.*, 2015a) and MSFragger (Kong *et al.*, 2017).

In addition, quantification of PTMs in large-scale studies using DIA has been reported with the tool called inference of peptidofoms (IPF), a fully automated algorithm that uses spectral libraries to query, validate and quantify peptidofoms in DIA datasets (Rosenberger *et al.*, 2017b).

Recent advances in instrumentation and development of dedicated software are making possible the characterization of proteomic samples by limiting or circumventing the enzymatic protein digestion. These approaches, referred to as middle-down and top-down, provide more complete sequence data, as oppose to bottom-up proteomics. Middle-down proteomics are hybrid methods, employing limited digestion to create large peptides which retain a richer sequence and PTM information and can be analyzed relatively easily by MS (Sidoli *et al.*, 2014). In top-down proteomics, high resolution MS/MS data is obtained directly from fragmentation of the intact protein (Smith and Kelleher, 2013; Zhang and Ge, 2011). Various software tools are available to analyze this type of complex spectra, adapted to the identification of proteofoms and PTMs, such as MS-Align + (Liu *et al.*, 2012), ProSight Lite (Fellers *et al.*, 2015), TopPIC (Kou *et al.*, 2016), MASH Suite (Cai *et al.*, 2016) and Informed-Proteomics (Park *et al.*, 2017).

Assessment of Error Rates in Identification Results and Protein Inference

Since only a fraction of all annotations generated by search engines are correct, proper assessment and control of error rates in identification results is a critical step in the informatics pipeline to distinguish correct from incorrect identifications. In proteomics, the most commonly used and accepted statistical confidence measure is the false discovery rate (FDR) (Benjamini and Hochberg, 1995) initially adapted by Elias and Gygi (2007) and also known as the “target-decoy approach” (TDA). In this strategy, a decoy database is first generated by reversing or shuffling the amino acids in the sequences of the reference or target database. All MS/MS spectra are searched against a composite target plus decoy protein sequence database, the best peptide match for each spectrum is selected for further analysis and the number of decoy peptide matches are used to estimate the fraction of incorrect annotations at given thresholds (Fig. 2, assessment and control of error rates).

The FDR analysis can be performed by the identification software or externally using stand-alone tools, represented in Table 2.

Table 2 Selected list of open source tools freely available for error rate assessment in identification results and protein inference

Software	Programming language	Features	Base modelling	Reference and website
PeptideProphet ^a	C++	Peptide FDR analysis	Target-decoy, mixture model, expectation-maximization	(Choi and Nesvizhskii, 2007; Keller <i>et al.</i> , 2002) http://tools.proteomecenter.org

iProphet ^a	C++	Peptide FDR analysis. Combination of results from multiple search engines	Target-decoy, mixture model, expectation-maximization	(Shteynberg <i>et al.</i> , 2011) http://tools.proteomecenter.org
Percolator	C++	Peptide and protein FDR analysis. Protein inference	Target-decoy, support vector machine	(Käll <i>et al.</i> , 2007; The <i>et al.</i> , 2016) http://percolator.ms
MAYU	Perl	Peptide and protein FDR analysis. Protein inference	Target-decoy, hypergeometric model	(Reiter <i>et al.</i> , 2009) http://proteomics.ethz.ch
PeptideShaker	Java	Peptide and protein FDR analysis. Combination of results from multiple search engines.	Target-decoy	(Vaudel <i>et al.</i> , 2015) http://compomics.github.io/projects/peptide-shaker.html
mProphet	Perl and R	Protein inference Peptide FDR for SRM, adapted later for DIA	Target-decoy, linear discriminant analysis	(Reiter <i>et al.</i> , 2011) http://www.mprophet.org/

^aAvailable through TPP.

The vast majority of the peptide FDR analysis tools utilize the target-decoy strategy. In the case of PeptideProphet, the initial parametric and unsupervised mixture model approach for posterior probability calculation was later combined with the target-decoy strategy within a single semisupervised framework (Choi and Nesvizhskii, 2007; Keller *et al.*, 2002).

Tools such as Percolator, MAYU and PepideShaker, also include the protein inference step to roll up identified peptide sequences into the corresponding proteins, and then calculate a statistical confidence score for each protein identification.

Inferring protein identities given a set of identified peptides is a difficult task due to several factors such as the presence of distinct proteins having a high degree of sequence homology and alternative splice forms of the same gene (Nesvizhskii and Aebersold, 2005).

It has been reported that the combination of several search engines further improves the results, by taking advantage of the specific strengths of each search engine to generate maximal results (Audain *et al.*, 2017; Kwon *et al.*, 2011; Shteynberg *et al.*, 2013). Tools like iProphet and PeptideShaker are of special considerations in the FDR analysis and necessary to properly combine multiple results while avoiding the accumulation of false positives from the different search engines.

Moreover, the FDR is a summary statistics for the entire identification results either at the PSM, peptide or protein level, however it does not indicate the identification confidence for a single hit at each level. There is a distinction between a global and local FDR. The global FDR is the fraction of incorrect hits among all hits that pass the threshold. The local FDR is the fraction of incorrect hits within a subset of hits that share the same score. In the data interpretation guidelines recently published by the Human proteome project (Deutsch *et al.*, 2016), detail reports of FDR values at each of the three levels are required for publication. The PSM-level FDR should be lower than the peptide-level FDR, which should be lower than the protein-level FDR. The larger the dataset, the more extreme these differences become. Extraordinary and novel detection claims require the evidence of two distinct peptides with length of nine amino acids or more.

Despite the FDR is a well-accepted concept, it has been reported that more advance statistical methods are needed in proteomics (Serang and Käll, 2015). An alternative to the target-decoy database approach was proposed and implemented in MSGF+, which uses E-values to evaluate statistical significance of individual PSMs through the generating function approach (Kim and Pevzner, 2014; Kim *et al.*, 2008).

The mProphet algorithms was originally implemented to automate data processing and statistical validation of large-scale selected reaction monitoring (SRM) experiments by scoring decoy transitions. Due to the similarity of the validation procedures, it has been extended and re-implemented in several tools for DIA.

Software to generate decoy spectral libraries are discussed in (Lisacek).

Quantification

Bioinformatics has played an essential role on the large-scale characterization of complex proteomes, traditionally by cataloguing proteins, and more recently, towards quantifying their expression profiles at different cellular states.

Due to differences in ionization efficiency, the signal detected by MS is not directly proportional to the protein concentration. Several combinations of analytical and computational methods have been developed and applied to quantify proteins by MS. Examples of studies evaluating quantification strategies include (Ahrné *et al.*, 2013; Blein-Nicolas and Zivy, 2016; Dowle *et al.*, 2016; Nahnsen *et al.*, 2013; Neilson *et al.*, 2011). **Table 3** shows a list of selected quantification software currently available.

Quantification methods can be label-free based or include stable isotope labels. Labeling methods are discussed in (Lisacek).

In label-free methods different samples are analyzed by LC-MS individually (**Fig. 2**, quantification), requiring reproducible chromatography and advanced informatics algorithms for retention time alignment across multiple samples and intensity normalization to minimize systematic biases. The so-called spectral counting technique has been conventionally used as a rapid and semi-quantitative measure of protein abundance based on the number of MS/MS spectra identified per peptide (Liu *et al.*, 2004). However, biological samples usually comprise a great variety of proteins across a wide dynamic range of abundances, where spectral counting has been found to often give irreproducible results, more notably for low abundance proteins (Cappadona *et al.*, 2012; Ahrné *et al.*, 2013; Blein-Nicolas and Zivy, 2016). In contrast, label-free methods based on the area under the peak or ion chromatogram provide a level of accuracy comparable to labeling approaches (Neilson *et al.*, 2011).

Multiple software packages are available to analyze the integrated peak areas and determine candidate proteins differentially expressed (**Fig. 2**, differential expression analysis). For instance, the R statistical package MSstats (Choi *et al.*, 2014) is a popular choice for analyzing DDA, DIA and SRM quantification results.

Data-Dependent Acquisition and MS1 Quantification

In shotgun proteomics, confidently identified peptides can be quantified using the continuous precursor ion signals from MS1 data or survey scans. MS1 quantification can be performed in two ways, differing in the approach used for chromatogram processing. One strategy, referred here as LC-MS feature-based, consists in first detecting and characterizing every LC-MS peak (often called LC-MS feature) in the MS1 data and then annotating them using the peptide identifications from the MS2 data. Among the first open source proteomics software implementing this approach are SuperHirn (Mueller *et al.*, 2007) and VIPER (Monroe *et al.*, 2007), and more recently MzMine 2 (Pluskal *et al.*, 2010). In contrast to attempt finding every MS1 peak, the second strategy is guided or targeted, i.e., extracted ion chromatograms (XIC or EIC) are constructed given a list of

Table 3 Selected software frameworks freely available for protein quantification

^aOpenSWATH.

mass-to-charge targets. Referred here as XIC-based, information from confidently identified peptides are used to extract the precursor ion signals of each peptide from the MS1 data. This is the case of Skyline, which compute the area under the peak from the XIC corresponding to each targeted peptide.

Data-Independent Acquisition and MS2 Quantification

DDA-based methods have been widely used to identify and quantify proteins. However, the semi-stochastic sampling in DDA leads to irreproducible results, particularly for highly complex proteomic samples. With recent developments in MS instrumentation and data analysis software, it has become practical the systematic and parallel fragmentation of all ions from peptides eluting during LC-MS analysis by DIA. These methods avoid the selection of individual peptide ions (Bilbao *et al.*, 2015a; Chapman *et al.*, 2014; Hu *et al.*, 2016). The label-free quantification performance of DIA methods has seen a growing popularity and adoption, providing a valid alternative to isotope-labeling-based methods (Navarro *et al.*, 2016).

DIA requires more sophisticated post-acquisition data analysis compared to DDA and several informatics tools have been developed to effectively process these complex datasets. The initial SWATH strategy (Gillet *et al.*, 2012) describing a targeted data extraction method using information from spectral libraries has been automated and improved in several tools: Skyline, DIANA (Teleman *et al.*, 2014), OpenSWATH (Röst *et al.*, 2014), SWATHProphet (Keller *et al.*, 2015). More recently, alternative workflows that circumvent the need of DDA for creating a spectral library have been developed: DIA-Umpire (Tsou *et al.*, 2015, 2016), GroupDIA (Li *et al.*, 2015), MSPLIT-DIA (Wang *et al.*, 2015) and Pecan (Ting *et al.*, 2017). A discussion about the challenges associated with error-rate control in the analysis of DIA data has been recently reported (Rosenberger *et al.*, 2017a).

Finally, a drawback of DIA is the increased likelihood of interference due to the overlap of fragment ions from co-fragmented precursors and several computational strategies can tackle this issue to further expand the benefits of DIA (Bilbao *et al.*, 2015b, 2016; Zhang *et al.*, 2015).

Selected Reaction Monitoring

Also referred to as multiple reaction monitoring (MRM), SRM is the MS method of choice to accurately and consistently quantify proteins across hundreds of complex samples. However, it is applicable when only a limited number of predefined proteins are compared. Therefore, it is typically used as the validation method, to confirm a list of target proteins obtained in a previous global or discovery study. For SRM data acquisition, the two mass filters of a triple quadrupole MS instrument select and monitor, over chromatographic elution, the signal of a series of transitions (precursor/fragment ion pairs and expected times) in a predefined list of target peptides (Lange *et al.*, 2008; Picotti and Aebersold, 2012).

Several informatics tools are available to assist the time-consuming process of defining the acquisition method. Examples of software to select proteins, proteotypic peptides, transitions and best acquisition settings include SRMcolider (Röst *et al.*, 2012), MRMOptimizer (Alghanem *et al.*, 2017), PREGO (Searle *et al.*, 2015) and the PNNL Biodiversity Plugin as one of the external tools available in Skyline (Degan *et al.*, 2016).

Since SRM data consist of a set of chromatographic traces for each monitored peptide, data analysis is simpler, compared to shotgun methods. The Skyline software tool is widely used for the integration of the chromatographic peaks for each transition, allowing the relative or, if heavy isotope-labeled reference standards are used, absolute quantification of the targeted peptides, which are used as a surrogate measure of the proteins of interest.

Alternatively, targeted MS methods such as parallel reaction monitoring (PRM) (Peterson *et al.*, 2012), use hybrid instruments where the third quadrupole is substituted with a high resolution and accurate mass analyzer, acquiring high-resolution full MS/MS spectra for each target peptide. Consequently, in PRM, the best fragment ions can be computationally selected post-acquisition. A web-based application for assay development was recently reported for targeted and label-free phosphoproteome analysis by PRM (Lawrence *et al.*, 2016).

Discussions regarding the best practices for targeted MS measurements in biology and medicine, including the computational and statistical tools, can be found in Carr *et al.* (2014).

How it all Fits Together

MS-based proteomics studies are supported by publicly accessible bioinformatics tools for processing and interpreting the large amounts of data that are generated in complex projects (Aebersold and Mann, 2016). To illustrate how various software tools are connected into processing pipelines, two recent representative applications are described.

The first study was based on MS1 quantification. Rieckmann and colleagues characterized 28 primary human hematopoietic cell populations in either steady or activated state (Rieckmann *et al.*, 2017). Measurements from three to four donors generated a total of 175 immune cell proteomes. Samples were analyzed by LC-MS with DDA and selection of the top-10 most intense precursor ions for fragmentation. Raw MS files were analyzed with MaxQuant. Identification was performed by the Andromeda search engine. The Label Free Quantification algorithm (MaxLFQ) was applied. Data analysis and visualization was performed using Perseus and R. More than 10,000 proteins were identified in total.

The second study was based on the SWATH strategy. Williams *et al.* (2016) analyzed phenotypes associated with liver mitochondrial metabolism. The authors profiled 386 individuals from 80 cohorts of the BXD mouse genetic reference population across two environmental states. Measurements in the livers of the entire population involved: transcriptome, proteome and metabolome. In particular for proteomics, a spectral library was built from a pooled sample analyzed by LC-MS with DDA and selection of the top-20 most intense precursor ions for fragmentation. Raw files were converted to mzML using AB Sciex Data Converter, applying the algorithm for centroid mode. Files were processed through TPP for identification. Search results were combined using iProphet and consensus spectra for a total of 22,208 peptides were constructed using SpectraST. Retention time was transformed to indexed retention time (iRT) (Escher *et al.*, 2012). The top-5 most abundant *b* and *y* fragment ions of each peptide were selected to generate the assays for the targeted data extraction. The DIA LC-MS analysis with SWATH was performed using a set of 32 overlapping isolation windows (width of 26 Da), covering the 400 to 1200 *m/z* precursor range. Raw files were converted to profile mzXML files using ProteoWizard. Targeted data extraction was performed using the OpenSWATH workflow. Identified peptides were analyzed with ProteinProphet. Peptide quantities and network graphs were calculated in R using the custom package imsbInfer (see Relevant Websites Section). A total of 2622 proteins were quantified in all 80 cohorts.

As it can be perceived, the processing and interpretation of hundreds of MS files and more than a million of spectra generated from these projects would have been impossible without bioinformatics tools properly assembled into workflows.

Related to network biology for MS-based proteomics (Fig. 2, protein network analysis), more information can be found in Bensimon *et al.* (2012). Examples of other available software include STRING (see Relevant Websites Section) as an online resource for querying and visualizing interaction networks and Cytoscape (Saito *et al.*, 2012; Shannon *et al.*, 2003) as one of the most popular open-source software for integration, visualization and analysis.

Closing Remarks

MS-based proteomics methodologies have evolved rapidly over recent years along with a remarkable progress on specialized software. These approaches are nowadays used in combination with other omics disciplines such as genomics, transcriptomics and metabolomics (Nesvizhskii, 2014; White *et al.*, 2017a,b). With the increasingly high throughput large scale studies in the big data era, robust and efficient MS software is as important as advanced MS hardware for comprehensively exploiting the information and generating knowledge. In this sense, progress in instrumentation and analytical methods are expected, and importantly, development of new computational methods to cope with these advances will continue to be an active area of research. Therefore, an increasing number of available tools including proprietary and open source can be expected.

The data processing workflow in MS-based proteomics is a set of consecutive complex tasks. It has been previously stated that this stepwise approach should be replaced by a joint model in which all relevant aspects of the experiment are taken into account (Noble and MacCoss, 2012). However, it is not possible tackling the complexity and variety of applications with a single joint model. Software modularity is thus required, yet, with high transparency and automation to support efficient integration of all available information. Open source software plays a key role towards this goal. Software modules with well-defined interfaces and input/output formats facilitate integration at different levels, avoiding information loss at every processing step and opens the

potential to integrate state-of-the-art machine learning to model dependencies among variables at the spectral, peptide, and protein level that are currently decoupled, as well as other relevant information such as clinical or environmental data. This is enhancing our understanding of the state of the proteome and its response to perturbations.

The diversity of questions possibly addressed with MS and the evolving technologies require software customization and/or extension. Robust open source software accelerates adaptations for technological innovations. For instance, the additional ion mobility (IM) dimension currently available in commercial instruments provides reproducible separation and structural information with numerous benefits in proteomic analyses (Baker *et al.*, 2015). However, this brings challenges for data processing because existing software tools for LC-MS data do not work. Skyline was updated to support LC-IM-MS and optimization of IM informatics is in progress for analysis of these large and multi-dimensional datasets (Pino *et al.*, 2017).

In this regard, several useful comments can be summarized about scientific software development. First, bioinformaticians are strongly encouraged to embrace practices that ensure software quality, sustainability and reproducible research (Jiménez *et al.*, 2017; Perez-Riverol *et al.*, 2016). Development of new algorithms and data analysis tools is challenging, it is a common practice developing prototypes first, with at least some basic design and testing. However, as soon as a software tool proves its usefulness, and before it is “too late” because it is too extensive and complex, time and effort must be dedicated for more testing, re-factoring and documentation. And this implies financial support.

Similarly, bioinformaticians are encouraged to join community efforts in order to avoid reinventing the wheel. Improving upon something is typically much easier than starting from scratch and allows for incremental progress, as one can see further by standing on the shoulders of giants. Crucially, any previous related work should be properly cited and acknowledged to avoid the term “research parasites”. This term has been recently and unjustifiably used for people reusing data (Martens and Vizcaíno, 2017), and should be also avoided for people reusing code.

Second, a software tool should have both command line functionality and GUI, either as stand-alone tool or integrated into current pipelines. Command line interfaces facilitate integration with other tools and are necessary for automation in large scale studies. On the other hand, a GUI expedites a quick execution in a few clicks, potentially increasing dissemination and number of users. In addition, the GUI facilitates testing, quality control, optimization of parameters and re-execution from any step to the end. Related to this point, visualization, at least as static figures in output files, is critical to support quick evaluation of results.

Third, a person other than the developer should try to follow the documentation (e.g., user guide, tutorial) and test the tool. The provided feedback will increase the robustness and usability. For instance, in a recent study of benchmarking DIA label-free quantification tools (Navarro *et al.*, 2016), feedback enabled developers to improve their software tools and after optimization, all tools provided highly convergent identification and reliable quantification performance. Documentation should include installation steps, software dependencies with versions, file formats and test data. Testing should be performed also with real data. For example, a simple approach producing acceptable results for a simple protein mixture, may produce poor results when processing a complex one such as a cell lysate.

Fourth, to ensure reproducibility, scientific articles related to both benchmarking and application studies should properly document the usage of any software, including details about the parameters and software version used, and data description with experimental and technical metadata related with the type of experiment. The metadata requirements for proteomics are in general much less comprehensive than those from more mature omics fields (Martens and Vizcaíno, 2017).

Finally, multidisciplinary collaborations will facilitate the design, implementation and validation of more advanced computational methods for proteomics and integration with other omics. Development of more powerful and user-friendly MS tools that can be used by researchers non-specialized in mass spectrometry or informatics is encouraged.

Introduction

Database is one of the most important innovation in computer science and information technology. Since its birth in 1960s, it has evolved many folds and is still evolving until today. Previously file based systems were used but were limited in its use due to issues such as data redundancy and inconsistency, difficulty in accessing data, data integrity and security, data isolation and many more. In order to resolve these concerns and limitations, the database approach was introduced and it was received well by the community. This is because database approach is more advanced, as the data is structured in a more formalised manner while the relationships between the data items are meaningful and consistent. Additionally, the database redundancy problem is very much minimised in databases compared to file based systems. In this way, the data can be used more efficiently either by automated or even manual systems. Database system applications are widely used in enterprises, banking and finance, universities, airlines, telecommunication and science due to the need for a computerised management of data which includes manipulation of data. Database systems promotes the use of advanced techniques such as data visualisation, data mining and data integration.

Currently in the era of data explosion, particularly in biology, the use and application of database technology is seen to be rising. Many areas such as bioinformatics, biodiversity and medical are applying the database technology to store, retrieve, manipulate and analyse data. The trend of big data has taken over conventional approaches in managing experimental data in biology. It is envisaged that a marriage between biology and database will soon churn out new trends, applications and discoveries.

This article presents the database fundamentals which includes different types of databases, the evolvement of biological databases, the approaches used in developing biological databases, some case studies using the approaches described, the results and discussion and finally the future direction of biological databases.

Database Fundamentals

Databases

In the simplest form, a database can be defined as an organised and formal collection of information stored in a computer readable format. In this section, some of the common approaches used in developing databases are presented.

Relational databases

The relational database has evolved over the years since its first introduction in 1970 and was largely adopted by industries across the world. Data in the relational model is usually represented by a structured schema ([Fig. 1](#)) in order to provide the data dictionary or metadata concerning the actual data ([Elmasri and Navathe, 2011](#)). Data which are represented by attributes are clustered based on the similarity, type and format in the form of columns of a table. The row on the other hand, represents the records in a database. A primary key is used to link data between multiple tables, whereas a foreign key is a reference to a primary key in another table. The data in a database is organised based on the relationships among the entities (and their corresponding attributes) while redundancy is minimized by performing data normalization.

Relational database comes with a default declarative language named Structured Query Language (SQL) developed at IBM by Donald D. Chamberlin and Raymond F. Boyce in the early 1970s. It provides interaction with structure data via CRUD (Create, Read, Update and Delete) statements and allows combination with multiple statement to perform more complex actions ([Cancelo, 2014](#)) ([Fig. 2](#)).

One of the main drawback of the relational model is that searching is burdened whereby the value being searched for is compared against every row in the table, from the first row to the last. This process is time consuming and has higher computational burden especially for large databases unless it uses other methods for searching such as indexes ([Segaran and Hammerbacher, 2009a](#)).

Multidimensional databases (OLAP)

In principle, a multidimensional database (MDD) is created using inputs from a relational database. In a MDD, data is stored in a cube, or a multidimensional array. When talking about MDDs, the term OLAP is prominent. The On-Line Analytical Processing (OLAP) is a term introduced by Dr. E.F. Codd ([Mallach, 2000](#)) which encompasses relational databases. The rule based OLAP system described by Dr. Codd are explained by [Pendse \(2008\)](#) formulating them into five simple definitions; Fast, Analysis, Shared, Multidimensional and Information. The OLAP is typically used in the business domain where it meets the needs of business analysts in business management, generating reports in addition to data mining. OLAP systems has also been used in

Fig. 1 An example of Entity Relationship Diagram using a relation schema.

Fig. 2 Example of an OLAP Model where data is represented in a cube dimensional model.

Biology, but are vaguely reported. Information stored in a MDD database are often used for effective decision making that usually deals with complex relationships with a short response time.

Graph and ontology based databases (NoSQL databases)

Ontology based databases are in principle made of the object oriented approach, where the datasets are treated as objects, with values and properties, similar to objects represented by object oriented programming like C++ and Java. Ontologies can be defined as formal representation of the types, properties, and interrelationships of the entities on a specific domain and form the basic component of the semantic web architecture. These entities, being linked with other entities by the means of relationships, lay the underlying foundation of the semantic web (Guarino, 1995). The ontologies, when linked with other ontologies, generate a network of nodes and relationships, laying the foundations of linked data (Heath and Bizer, 2011).

The ontology development in a particular domain is facilitated by standardization of vocabulary that is accepted and used by domain experts. These vocabularies are shared for reuse, monitored by a body of experts to oversee the development of such vocabularies. An ontology can enhance information providing capability for a database by the use of metadata to discover and gather new information from other databases, or by linking them to create a better information network. An ontology can also be used as an underlying framework for building a database (Abu et al., 2013a,b; Ali et al., 2017).

NoSQL is a term used to refer to schemaless databases, which do not fit within the traditional relational paradigm. It describes a new category of non-relational databases, which are also known as distributed data stores that are capable of scaling to large datasets spanning to multiple data centres (Ercan, 2014). Recently, NoSQL database systems started to receive much attention as the demand increases for high speed data access over large volume of data without much effort in scaling and tuning (Ferreira et al., 2013). NoSQL architecture is designed to overcome the limited scalability, flexibility, performance, availability, and infrastructure cost issues associated with relational databases (Stonebraker, 2009). They depend on horizontal scalability which scales performance and capacity by increasing the number of nodes, instead of increasing the computer power of a single node as seen in relational databases (Abramova and Bernardino, 2013). An example of a no SQL database is a graph database Fig. 3. Data are stored as graph in the form of nodes (objects) and edges (relationships). The primary goal is to visualize the relationships between nodes. There are now many tools available to design and develop moSQL databases, such as Neo4j (2018) and MongoDB (2018).

Graph databases, which forms the base for noSQL databases use a graph model for semantic queries with nodes, edges and properties to represent and store data. Unlike the relational structures, in graph dabases, millions of connections can traversed

Fig. 3 Graph data model representing the nodes (in oval), relationships (arrows). The descriptive boxes showing the mainly properties in nodes and edges. Source: Costa, R.L., Gadelha, L., Ribeiro-Alves, M., Porto, F., 2017. GenNet: An integrated platform for unifying scientific workflows and graph databases for transcriptome data analysis. PeerJ, 5, p. e3509.

per second per core (Neo4j, 2018). Having a conceptual design, similar to network-model databases in 1970s, graph databases excel at managing linked data and complex queries, independent of the total size of the dataset (Angles and Gutierrez, 2008). Graph databases explore the larger neighborhood around the initial starting points with a pattern and a set of starting points by collecting and aggregating information from thousands or millions of nodes and relationships (Neo4j, 2018). Contrary to relational databases that operate with SQL language, in graph databases, there is no single query language that operates in same fashion as SQL. Query languages such as Gremlin, SPARQL, and Cypher can be used to access graph databases using application programming interfaces (APIs) (Wood, 2012).

Spatial databases

Data in a geometric space contains objects such as coordinates, points, lines, polygons and regions are stored in a spatial database as in objects, rather than pictures or images of a space. It is important to note that spatial databases are different from image databases. The data model encompasses the spatial data types (SDTs) which is used as underlying framework to construct Geographic Information Systems (GIS). Typically, spatial databases uses the relational schema discussed in Section “Relational databases”.

Database System Architectures

Distributed databases

In a typical distributed databases environment, the databases are stored on several computers, which are interconnected via a communication media such as a network connection. These databases are loosely coupled in terms of physical specifications and hardware however in terms of the design schema they might have both a local schema and a global schema. A local schema is unique to a particular database whereas a global schema is used to connect all the databases to achieve a specific goal. Distributed databases are also used in situations where there is an attempt to link or integrate a few existing databases, which are built upon different formats or using different architectures. The reason behind a potential integration could be to share the data stored in these distributed databases.

A general structure of distributed database is shown in Fig. 4.

Federated databases

In a federated database environment, several homogeneous or heterogeneous databases are harmonised to function as a single entity in a unified view, through a common structured metadata. Each of the constituent database serves as a distinct, self-sustainable and autonomous component in the federated system. These components acts as nodes in a computer network and may be geographically decentralized. Federated database is one of most common mainstream model in life sciences data integration. An example of federated database architecture is shown in Fig. 5.

Data warehouse

A data warehouse is a repository for storing data which may have been gathered from a source or multiple sources, manually or automatically, via an integration layer that transforms data to meet the criteria of the warehouse. Data warehouse can be

Fig. 4 Distributed Database Structure. The nodes (computers) storing database A, B, and C are distributed and connected via the network.

Fig. 5 Federated Database Architecture.

Fig. 6 Data Warehouse Architecture.

conceptualised as a one stop information center large volume of data which is designed under a common framework. In a centralized data warehouse, since data is unified and in homogeneous format, queries are easier to write and gives user better performance than accessing multiple distributed data warehouses. Integration of data in bioinformatics data warehouse and the issues affecting the integration has been presented by [Kormeier \(2014\)](#). An example of data warehouse architecture is shown in [Fig. 6](#).

Uses of Databases

The role of database has evolved from a stand alone specialised system into an integral component of an advanced and sophisticated computing environment. Conventionally, databases were constructed for storage, retrieval and manipulation of data. Today, the role has gone far beyond to knowledge extraction, data mining and visualisation.

Knowledge extraction

Databases are built to support front end applications which ranges from simple query based systems to sophisticated artificial intelligence enabled systems. With the concept of big data that has taken Information Technology into a new era altogether, databases are extensively used for knowledge extraction using algorithms that are run through large volumes of data. Thus, databases now have bigger role to play in many data centric domains to function as platforms for machine readable and machine interpretable format of information. Thiele *et al.* (2010) presented an interesting tool, the Protein Information and Knowledge Extractor (PIKE) which allows researchers to extract information from genomics and proteomics databases. Another good example is Lynx (see “Relevant Websites section”), a database and knowledge extraction engine for integrative medicine (Sulakhe *et al.*, 2016). Thessen and Parr (2014) presented a method on knowledge extraction and semantic annotation of text from the Encyclopedia of Life (Parr *et al.*, 2014).

Data mining

Databases are very useful for storing massive and ever growing amount of data, which can be utilised for discovering patterns and rules, automatically or even semi-automatically. This method is widely known as data mining and is conceived based on logics in database systems (Paramasivam *et al.*, 2014). A clean set of integrated data is usually stored in a data warehouse before the data mining techniques are applied. Some of the key techniques commonly used in data mining include classification, clustering, prediction, association, text mining, link analysis and regression. Data mining is seen as an important concept in databases as the process involves collecting data, creating database and management, analyzing data and finally interpreting data (Han *et al.*, 2000).

Visualisation

Visualizations can be used to interpret meaning from data through comprehension and exploration as large part of human nervous system has evolved to process visual information (Segaran and Hammerbacher, 2009b). An effective visual design aids decision making and interpretation to generate knowledge. One of the main component of data visualisation is the primary data, which conceived in a data warehouse. A data visualisation software or a script can be used to find pattern, correlations or trends to generate knowledge, which could not be seen in textual or numerical content in a database. One good example of data visualisation is using graph based databases whereby the data is retrieved in a visual context.

Biological Databases

Since its birth, database has become a core element of any discipline that produces large amounts of data. In Biology (particularly in genomics), massive amounts of data are being accumulated on a daily basis via experimental work, field work, software analysis, illustrations, microscopic photographs and image acquisition. Stephens *et al.* (2015) compared other Big Data Domains such as, astronomy, youtube and twitter in their recent study on Genomics perceiving to be Big Data science (Fig. 7). They estimated that genomics is leading or at par with the other big domains in terms of terms of data acquisition, storage, distribution, and analysis. Hence, the need to accommodate the data surge in biology is a challenge. This scenario has lead to the construction of not only single databases but also the consortiums managing large amounts of biological data.

Data Phase	Astronomy	Twitter	YouTube	Genomics
Acquisition	25 zetta-bytes/year	0.5–15 billion tweets/year	500–900 million hours/year	1 zetta-bases/year
Storage	1 EB/year	1–17 PB/year	1–2 EB/year	2–40 EB/year
Analysis	In situ data reduction	Topic and sentiment mining	Limited requirements	Heterogeneous data and analysis
	Real-time processing	Metadata analysis		Variant calling, ~2 trillion central processing unit (CPU) hours
	Massive volumes			All-pairs genome alignments, ~10,000 trillion CPU hours
Distribution	Dedicated lines from antennae to server (600 TB/s)	Small units of distribution	Major component of modern user's bandwidth (10 MB/s)	Many small (10 MB/s) and fewer massive (10 TB/s) data movement

doi:10.1371/journal.pbio.1002195.t001

Fig. 7 Four domains of Big Data in 2025. Source: Stephens, Z.D., Lee, S.Y., Faghri, F., *et al.*, 2015. Big data: Astronomical or Genomical? PLOS Biology 13(7), e1002195. Available at: <https://doi.org/10.1371/journal.pbio.1002195>.

The most current online biological databases can be found in the yearly issue of the journal *Nucleic Acids Research* (NAR: see “Relevant Websites section”) and *The Journal of Biological Database and Curation* (DATABASE: see “Relevant Websites section”). Both these journals are freely published by the Oxford Academic Journals (see “Relevant Websites section”). Another important source of biological databases is the BMC Bioinformatics (see “Relevant Websites section”).

In this section, a range of biological databases is presented. Biological databases are defined under three broad categories which are primary databases, secondary databases and specialised databases. Types of biological data includes (but not limited to): nucleotide and protein sequences (b) protein structure (c) microarray and gene expression (d) metabolic pathways (e) species profile (taxonomy) (f) animal model (g) human disease (h) clinical database and others.

Primary Databases

Nucleotide sequence databases were propelled by the necessity to store primary experimental data for further analysis in Bioinformatics. Major sequence databases include the European Nucleotide Archive (ENA) (see “Relevant Websites section”) (Rasko *et al.*, 2011), GenBank (see “Relevant Websites section”) (Benson *et al.*, 2008) and the DNA Data Bank of Japan (DDBJ) (see “Relevant Websites section”) (Jun *et al.*, 2017) and EMBL Nucleotide Sequence Database (see “Relevant Websites section”) (Kanz *et al.*, 2005). These databases are matured sequence databases with search functionality and basic Bioinformatics tools, which are useful to the Bioinformatics community.

A variety of primary sequence databases exist and are widely used in bioinformatics. A significant contribution was made by UniProt (see “Relevant Websites section”) to combine Swiss-Prot, TrEMBL and PIR-PSD protein sequence databases into a unified view. The widespread protein aid (uniprot) is a complete resource for protein sequence and annotation statistics. The uniprot databases consists of uniprot knowledgebase (uniprotkb), the uniprot reference clusters (uniref), and the uniprot archive (uniparc) (Uniport, 2017). Protein Data Bank (PDB: see “Relevant Websites section”) is one of the oldest database that contains database containing experimentally determined three-dimensional structures of proteins, nucleic acids and other biological macromolecules (Burley *et al.*, 2017).

Microarray database contain microarray gene expression data, which can be further analysed, and interpreted. Recently microarray databases have become very popular with the emergence of high-throughput technology, enabling the expression for thousands of genes simultaneously. Example of very common microarray databases are ArrayExpress (see “Relevant Websites section”) from EBI (Brazma *et al.*, 2003) and GEO (Gene Expression Omnibus) (see “Relevant Websites section”) from NCBI (Barrett *et al.*, 2006) and the Stanford Microarray Database (see “Relevant Websites section”) (Sherlock *et al.*, 2001).

As an important and one of the most studied branch of Biology, biochemistry related databases have emerged, such as the metabolic pathway databases. A few good examples are BRAunschweig ENzyme Database, BRENDA (see “Relevant Websites section”) (Schomburg *et al.*, 2002), KEGG PATHWAY Database (see “Relevant Websites section”) (Kanehisa and Goto, 2000) and Metacyc (Caspi *et al.*, 2007).

Phylogenetics is the study the evolutionary history and relationships among individuals or groups of organisms. Despite being one of the important aspect of Biology, there are not many databases available online for phylogenetics. There are two databases worth mentioning which are Phylomedb (see “Relevant Websites section”) (Huerta-Cepas *et al.*, 2010), a public database for complete catalogs of gene phylogenies (phylomes) and treebase (see “Relevant Websites section”) (Sanderson *et al.*, 1994).

Secondary Databases

Secondary databases are more focused as these databases contain derived data (by analyzing primary data) to address specific requirements. This section presents significant and popular secondary biological databases which are well represented in their domain.

The Eukaryotic Promoter Database (EPD: see “Relevant Websites section”) comprehensive organisms-specific transcription start site (TSS) collections automatically derived from next generation sequencing (NGS) data (Dreos *et al.*, 2016).

NCBI Reference Sequence Database (RefSeq (see “Relevant Websites section”)) is a comprehensive, integrated, non-redundant, well-annotated set of reference sequences including genomic, transcript, and protein (Pruitt, 2006).

Pfam (see “Relevant Websites section”) is a database of protein families that consists of their annotations and a couple of series alignments generated using fashions. The most current version, Pfam 31.0, was launched in March 2017 and incorporates 16,712 families (Finn *et al.*, 2017a,b). Pfam has moreover been used inside the advent of different assets which includes ipfam, which catalogs region-area interactions inside and between proteins, based totally on information in structure databases and mapping of Pfam domain names onto those structures (Xu and Dunbrack, 2012).

Prosite (see “Relevant Websites section”) is a protein database, which includes entries describing the protein families, domains and practical websites in addition to amino acid styles and profiles in them, manually curated via a team of the Swiss Institute of Bioinformatics and tightly included into Swiss-Prot protein annotation. Prosite was developed in 1988 by Amos Bairoch, who also directed the institution for more than two decades (Prosite introduction, 2017).

The PRIDE PRoteomics IDentifications (PRIDE) (see “Relevant Websites section”) is a data warehouse on proteomics data, including protein and peptide identifications, post-translational modifications and supporting spectral evidence.

SCOP2 (see “Relevant Websites section”) is a successor of Structural classification of proteins (SCOP) focusing on proteins that are structurally characterized and deposited in the PDB. These proteins are organised according to their structural and evolutionary relationships in a complex graph network. Each node represents a relationship of a particular type and is exemplified by a region of protein structure and sequence (Andreeva *et al.*, 2013).

CATH (Class, Architecture, Topology, Homology) (see “Relevant Websites section”) is a protein structure classification database containing annotations for over 235,000 protein domain structures and includes 25 million domain predictions (Sillitoe *et al.*, 2014).

Protein-protein interaction database are useful source of secondary databases. Two major works in this area include BioGRID and STRING. The Biological General Repository for Interaction Datasets (BioGRID: see “Relevant Websites section”) is a public database of genetic and protein interactions curated from the primary biomedical literature for model organism species and humans (Chatr-Aryamontri *et al.*, 2014) whereas the Search Tool for the Retrieval of Interacting Genes (STRING: see “Relevant Websites section”) contains the Predicted functional associations between proteins (Szklarczyk *et al.*, 2014).

Specialised Databases

Other than the above mentioned categories, there are specialised biological databases available for the scientific community. A few examples are Phylogenomic Database for Plant Comparative Genomics (GreenPhylDB: see “Relevant Websites section”), the Plant Secretome and Subcellular Proteome Knowledgebase (PlantSecKB: see “Relevant Websites section”), TreeBASE (see “Relevant Websites section”), an open-access database of phylogenetic trees and associated data, the Plant Alternative Splicing database (PASD: see “Relevant Websites section”), Comparative Toxicogenomics Database (CTD: see “Relevant Websites section”), Drosophila Genes & Genomes (FlyBase: see “Relevant Websites section”), WormBase (see “Relevant Websites section”), AceDB (see “Relevant Websites section”), the Arabidopsis Information Resource (TAIR: see “Relevant Websites section”), Online Mendelian Inheritance in Man (OMIM: see “Relevant Websites section”) which is an online catalogue of human genes and genetic disorders and the *Saccharomyces* Genome Database (SGD: see “Relevant Websites section”).

Integrated Databases

Integrated databases are databases that are unified under a platform, with the aim to offer a suite of applications for secondary uses of the data. These days integrated databases are preferred by researchers due to their usability as one stop centres for knowledge extraction. A large number of biological databases are produced or are managed by the National Center for Biotechnology Information (Coordinators, 2016), which contains a myriad of biological content. Other initiatives are the Kyoto Encyclopedia of Genes and Genomes (KEGG: see “Relevant Websites section”), GeneCards (see “Relevant Websites section”), the InterPro Consortium (Finn *et al.*, 2017a,b), the European Molecular Biology Laboratory (EMBL) Nucleotide Sequence Database (see “Relevant Websites section”) and the Global Biodiversity Information Facility (GBIF: see “Relevant Websites section”). These databases are more like consortiums managing and integrating sources of information to provide a unified access to users.

Other Biological Databases

Biodiversity (taxonomy) databases

Taxonomy databases, also referred as biodiversity databases have been developed much before sequence databases are introduced. Taxonomy, being a very old and matured branch of Biology, has produced abundant of data, particularly on species profiling. Almost every country listed as a megabiodiversity country has produced a database of their very own indigenous organisms. Some of the most important biodiversity initiatives are started by GBIF (see “Relevant Website section”), Taxonomic Data Working Group (TDWG: see “Relevant Websites section”) and Encyclopedia of Life (EoL: see “Relevant Website section”). These global initiatives encourage sharing of biodiversity data which was previously stored in data silos managed by smaller groups. The unprecedented volume of biodiversity data has caused a momentous increase in the number of online biodiversity databases hosted in separate infrastructure which are managed by research groups. Example of some very popular databases include the Catalogue of Life (see “Relevant Websites section”), Integrated Taxonomic Information System (ITIS: see “Relevant Websites section”) and FishBase (see “Relevant Websites section”).

Animal model database

Animal models are mostly used in biomedical research which is an important research area to demonstrate biological significance in experiments. Due to this, animal model, particularly mouse model databases are adevent these days. A few examples are mentioned here to demonstrate the kind of databases produced in this domain.

The MUGEN mouse database (MMdb: see “Relevant Websites section”) is a repository of murine models of immune processes and immunological diseases.

Mouse Genome Informatics (MGI: see “Relevant Websites section”) MGI is the international database resource for the laboratory mouse, providing integrated genetic, genomic, and biological data to facilitate the study of human health and disease.

The Mouse Phenome Database (MPD: see “Relevant Websites section”) is one of the most widely used resource for primary experimental trait data and genotypic variation.

International Mouse Strains Resource (IMSR: see “Relevant Websites section”) is a database on mouse strains, stocks, and mutant ES cell lines available worldwide, including inbred, mutant, and genetically engineered strains.

Other mouse model databases are The European Mouse Mutant Archive (see “Relevant Websites section”) and the Rat Resource and Research Center (see “Relevant Websites section”).

Besides mouse, other animals database on Zebra, Zebrafish and Drosophila have been published. One good example is the Zebrafish models (ZF-Models: see “Relevant Websites section”), which is an information system on zebrafish that can be referred for producing and identifying disease models, drug targets and insight into pathways of gene regulation applicable to human development and disease. Other examples are Zebra International Resource Center (see “Relevant Websites section”) and Bloomington Drosophila Stock Center (BDSC: see “Relevant Websites section”).

Clinical/health database

Clinical and Health databases must not be sidelined in the discussion about biological databases. While we will not be able to mention all the works done in this area, it is crucial to highlight a few significant examples to demonstrate the kind of databases produced for this purpose. The National Center of Biotechnology Information (NCBI), as part of their database initiative, has produced two important clinical and health databases which are ClinVar (see “Relevant Websites section”), a database on the reports of the relationships among human variations and phenotypes; and MedGen (see “Relevant Websites section”) a database containing information related to human medical genetics, such as attributes of conditions with a genetic contribution. Database of Genotypes and Phenotypes (dbGaP: see “Relevant Websites section”) is an archive of data and results from studies that have investigated the interaction of genotype and phenotype in humans. PubMed Health (see “Relevant Websites section”) is the world’s largest digital medical library. MEDLINE (see “Relevant Websites section”) contains journal citations and abstracts for biomedical literature from around the world while PubMed (see “Relevant Websites section”) is an archive of more than 28 million citations (links to full text content from PubMed and publisher websites) for biomedical literature from MEDLINE, life science journals, and online books.

Clinical and Health databases focusing on diseases are also useful resource for biologists and medical scientists. There are some prominent disease databases published online such as MalaCrads (see “Relevant Websites section”), the Autoimmune Disease Database (see “Relevant Websites section”), Inflammatory Bowel Diseases (IBD: see “Relevant Websites section”), KEGG Disease Database (see “Relevant Websites section”) and LiverWiki (see “Relevant Websites section”), a wiki-based database for human liver. The Diseases Database ver 2.0 contain a whole range of database in their portal, which is available at the website provided in “Relevant Websites section”. Finally, a comprehensive collection of human related biological databases is presented by [Zou et al. \(2015\)](#).

Biological Databases Case Studies: Genecards and Cancer Genome Atlas

Genecards (see “Relevant Websites section”)

In the early 80s, storing sequence data was not easy due to cost and infrastructure limitations. Nevertheless, many institutions have started to store their data in primary databases which are available in isolated platforms and are focused on specific subject of study. In order to gather these scattered data, The Weizmann Institute of Science Crown Human Genome Center (<http://www.weizmann.ac.il>) developed a database called *GeneCards* in 1997. In the early stage, this database was dealing mostly with human genome information, human genes, the encoded protein’s function and related diseases.

Later, it incorporated automatically-mined genomic, proteomic and transcriptomic data, as well as orthologies, disorder relationships, snps, gene expression, gene characteristic, and hyperlinks for ordering assays and antibodies ([Genecards, 2018](#)). Currently it serves as a complete, authoritative compendium of annotative information about human genes that has been broadly used for almost 15 years ([Safran et al., 2010](#)). Genecards has blossomed into a collection of equipment (along with Genedecks, Genealacart, Geneloc, Genenote and Geneannot) for a spread of analyses of each single human genes and units due to its viewing information and deep links associated with unique genes and constant improvements, over the years. ([Stelzer et al., 2011](#)) (**Figs. 8–11**).

GeneCards versions

GeneCards Version 1.xx- contained gene-centric information, automatically mined and integrated from a myriad of databases resulting in a web-based *card* for each of human gene entry ([GeneCards, 2018](#)).

GeneCards Version 2.xx- the information is stored in flat files, one file per gene, all indexed to enable full-text searches ([GeneCards, 2018](#)).

GeneCards Version 3.xx- introduced a persistent object/relational model of all the data entities and relationships displaying diverse functions of single genes by extracting various slices of attributes of the genes ([GeneCards, 2018](#)). It also hosts the new seek facility by offering hyperlinks to a sample gene and its diverse sections ([Safran et al., 2010](#)).

GeneCards Version 4.xx- the hybrid system is eliminated, moving to a robust infrastructure based entirely on a new and well defined relational database ([GeneCards, 2018](#)).

GeneCards applications

GeneDecks exploits Genecards unique wealth of combinatorial annotations to discover similar (associate) genes, and to perform quantitative descriptor enrichment analyses for figuring out set-shared annotations. Some of these functions are available online, through the Genecards website, while others independent studies. Some of the Genecards applications are described below.

SYNLET – Regulatory control networks of synthetic lethality via Genedecks mainly addresses robustness of phenotypic characteristic on the basis of artificial lethality, as proposed for novel most cancers remedy regimes. It derives novel standards, methodologies and algorithms for annotation and evaluation of regulatory networks, with attention on tumorigenesis and drug resistance. It aims

The screenshot shows the GeneCards website interface. At the top, there is a navigation bar with links to GeneCards, MalaCards, LifeMap Discovery, PathCards, TGex, VarDict, GeneAnalytics, GeneAlaCart, and GenesLikeMe. Below this is a search bar with a 'Keywords' dropdown and a 'Search Term' input field. The main content area features the GeneCards logo and a description: 'GeneCards is a searchable, integrative database that provides comprehensive, user-friendly information on all annotated and predicted human genes. It automatically integrates gene-centric data from ~125 web sources, including genomic, transcriptomic, proteomic, genetic, clinical and functional information.' A large orange circular icon with a DNA helix is also present. Below the description is a section titled 'Explore a Gene' with a search bar containing 'ADAM10' and a 'GO' button. Underneath, there are links to 'Jump to section for this gene:' including Aliases, Disorders, Domains, Drugs, Expression, Function, Genomics, Localization, Orthologs, Paralogs, Pathways, Products, Proteins, Publications, Sources, Summaries, Transcripts, and Variants. On the right side, there are sections for 'NGS Analysis Tools' (TGex, VarDict), 'Affiliated Databases' (MalaCards, LifeMap, PathCards, GeneLogic), and 'Analysis Tools' (GeneAnalytics, GeneAlaCart, GenesLikeMe, GeneHancer). At the bottom, there is a 'GeneCards Database Statistics' table.

GeneCards Database Statistics				
		Category	# of Genes	Example Genes
Total GeneCards genes	147,013	Protein-coding	21,360	PDGFRA, ERBB2, ERBB4, ESR1, FGFR1, FGFR2, FGFR3, MET, PDGFRB, CDK4
HGN Approved genes	41,298	RNA genes	98,609	HCP5, DSCR4, C9orf31, MEG3, PRNT, RUSC1-AS1, TERC, DLEU1, C10orf91, C13orf54
Disease genes	11,483	Pseudogenes	16,337	GNRHR2, GUCY1B2, LPAL2, ABCG13, PPP4R1L, PRKY, HLA-H, KIR3DX1, MMP23A, SERHL
Hot genes	500	Genetic loci	1,819	DYX1, ST2, AAVS1, IFNR, NM, AZF1, BCL5, FRAXA, ST3, ST8
		Gene Clusters	18	PCDHA@, IGLV@, RNSS1@, PCDHG@, IGKV@, PCDHB@, SNORD116@, HCCA@, HOXD@, HOXS@
		Uncategorized	9,770	C20orf181, ERYMR1-1, TRAV35, TRBV11-2, ENSG00000235978, TRAJ15, WBSGF2, TRAJ8, PCDHACT, ENSG00000254859

Fig. 8 The screenshot image of the domain GeneCards, human genome database. Retrieved from: <https://www.genecards.org/>.

to explore key proteins of cellular escape mechanisms that conquer lethality of medicine and find approaches to block them, utilizing siRNA. Genedecks became one of the major equipment which served the consortium to choose candidates for the siRNA experiments. The set distiller mode of Genedecks permits the identification of annotation descriptors shared via experimentally-received gene sets, permitting the evaluation in their belonging to precise practical lessons, for this reason a really appropriate choice of inactivation targets (Safran *et al.*, 2010).

SysKid – Systems biology towards novel chronic kidney disease diagnosis and treatment explores chronic kidney ailment, with diabetes mellitus and high blood pressure being the maximum widely wide-spread causative conditions. It assumes that despite it being numerous in etiology, the underlying molecular pathophysiology of different manifestations of this condition can be similar. The venture goals at acquiring a unified view on the disease within the scope of systems biology, primarily based on high-throughput omics analysis. The Genecards version 3.xx database and superior seek engine are instrumental for the combination procedure and in figuring out the maximum promising sickness markers (Stelzer *et al.*, 2011). For instance, Genecards might be used to perceive applicable genes for metabolomics hints. In this framework, a 'Genecards 100k' attempt is presently beneath way, aiming at increasing the range of gene entries closer to one hundred 000. This will be finished mainly through a big growth of Genecards' scope within the realm of non-protein-coding RNA genes, and resolving a massive wide variety of genes currently entitled 'uncategorized'. In parallel, a challenge-particular database (Genekid) could be created, to residence incoming omics facts in Genecards-well suited tables, for that reason facilitating the systems biology analyses (Safran *et al.*, 2010).

Future of genecards

The success of applications described above will further upgrade GeneCards core features. An exciting destiny undertaking is to plot a set of rules for unifying disorder names/descriptions and permit those tables to be merged. An increase in pathway repertoire and inclusion of public area (e.g., reactome) and/or additional industrial pathways are expected. In the future, the 'feature' phase will also consist of animal models from species other than mouse (Safran *et al.*, 2010).

The Cancer Genome Atlas (TCGA) (see "Relevant Websites section")

The National Institutes of Health (NIH) mounted The cancer Genome Atlas (TCGA) to generate complete, multi-dimensional maps of the important thing genomic changes in important types and subtypes of cancer (National Institutes of Health, 2017).

SYNLET Project

Project Summary

This project addresses robustness of **phenotypic function** on the basis of highly interlinked **network topologies** on a very practical level: **Synthetic Lethality** – as proposed for novel cancer treatment regimes. Function in this context is the property of transformed cells to continuously divide, and robustness is encoded by regulatory elements on the genomic and proteomic level triggering drug treatment escape as an emergent property: chemotherapy resistance. This project will derive novel concepts, methodologies, and their algorithmic implementation for annotation and analysis of general regulatory networks - with particular focus on network robustness and escape routes toward maintaining function. In parallel, computational genomics will be applied on a gene expression data set derived from a unique, systematic collection of chemotherapy resistant cancer cell lines. These real world data encode a set of regulatory escape mechanisms to overcome the lethality imposed by a specific drug. The general concepts and approaches – focusing on dynamical levels – will subsequently be calibrated and merged with results from computational genomics – focusing on a static system representation – to gain insight into the mechanisms of cancer cell robustness, but in particular to identify key proteins of cellular escape mechanisms to overcome lethality of drugs. Blocking these proteins may result in synthetic lethality including re-sensitization of chemoresistant cancer cells to cytotoxic drugs. To prove the validity of our Complex Systems Analysis approach we will test generated hypotheses on synthetically lethal hubs in the cellular control network via experimental knock down experiments utilizing siRNA.

EU foundation

Proposal Full Title	Regulatory Control Networks of Synthetic Lethality
Proposal Acronym	SYNLET
Date of Preparation	February 15, 2006
Version No.	2.0
Type of Instrument	Specific Targeted Research Project
Submission Stage	Full Proposal
Activity Code Addresses	NEST-2005-Path-COM

Coordinator:
Dr. Michaelis Martin

The Cancer Genome Atlas (TCGA) is a venture began in 2005, to catalogue genetic mutations answerable for cancer, the usage of genome sequencing and bioinformatics. TCGA applies excessive-throughput genome analysis strategies to enhance the ability to diagnose and treat cancer via a detailed investigation of the genetic basis of this ailment (Tomczak *et al.*, 2015; The National Genome Atlas, 2017).

In 2006, TCGA targeted on characterization of 3 varieties of human cancers: Glioblastoma Multiforme, lung, and ovarian cancer. This attempt initiated by NCI and NHGRI in 2006 developed the rules, production pipeline, collaborative studies network, databases and analytical equipment important for TCGA's big-scale analysis of cancer genomics. The pilot's characterizations of brain tumours and ovarian cancer have proven that this systematic, excessive-quantity approach can generate excellent novel discoveries, useful for scientific researchers around the globe (The National Genome Atlas, 2017).

In 2009, TCGA accelerated into Phase II, which planned to complete the genomic characterization and collection evaluation of 20–25 special tumour types through 2014. TCGA passed that aim, characterizing 33 cancer types together with 10 rare cancers. The project was split between genome characterization centres (GCCs), which carry out the sequencing, and genome records analysis facilities (GDACs), which carry out the bioinformatics analyses (The National Genome Atlas, 2017). With its pipeline in area, TCGA correctly acquired samples of tumours and coupled ordinary tissue, rapidly sequenced the DNA and RNA of the samples, and comprehensively characterized the genomes the usage of seven genomic platforms (The National Genome Atlas, 2017).

In December 2013, while TCGA finalized its collection of matched tumour and everyday samples, sufficient tissue have been accumulated to map the genomic traits of extra than 30 cancer types. TCGA evaluation operating agencies, groups of scientists from across the United States of America, have now comprehensively studied 33 cancer types and subtypes, along with 10 rare cancers (The National Genome Atlas, 2017).

This pioneering effort to map and analyse most cancers genomes in a huge-scale, systematic way has modified the way most cancers are studied, and could ultimately rework the way most cancers are dealt with because TCGA information is loose to use, it significantly reduces the costs and expedites the manner of drug development, allowing both public and private quarter researchers

to pursue centred cures geared toward the precise pathways in a positive most cancers kind or subtype. This new level of insight, supplied by means of TCGA will chart a brand new path for most cancers research and pioneer the manner to extra effective, individualized techniques for helping every affected person with most cancers (The National Genome Atlas, 2017).

Fig. 11 The Cancer Genome Atlas (TCGA) Research Network Centres flowchart. Available from: <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4322527/figure/F0001/>.

The TCGA initiative scheduled 500 affected person samples and used distinctive strategies to investigate the patient samples. Techniques include gene expression profiling, reproduction quantity version profiling, SNP genotyping, genome huge DNA methylation profiling, microRNA profiling, and exon sequencing. TCGA is sequencing the whole genomes of some tumours, which include at least 6000 candidate genes and microRNA sequences. (The National Genome Atlas, 2017).

This catalogue serves as an effective useful resource for a brand new generation of research aimed towards developing higher strategies for diagnosing, treating and preventing most cancers. TCGA also presents a version for plenty different genome mapping projects (National Cancer Institute, 2017).

Mutually led via the countrywide cancer Institute (NCI) and the country wide Human Genome Research Institute (NHGRI), TCGA is changing the manner genetic most cancers studies are completed. Following the instance set with the aid of the Human Genome undertaking, TCGA's collaborative studies network has added together researchers from diverse disciplines and more than one establishment to provide precious statistics units to be used by using the worldwide studies community (The National Genome Atlas, 2017).

The shape of TCGA is properly organised and includes several cooperating centres liable for collection and sampleprocessing, observed through high-throughput sequencing and sophisticated bioinformatics data analyses.

First, special tissue supply websites (TSSs) accumulate the desired bio specimens (blood, tissue) from eligible cancers patients and deliver them to the Biospecimen Core Resource (BCR). Subsequently, the BCR catalogue validates and then submit the scientific data and metadata to the Data Coordinating Center (DCC) and provide molecular analyses for the Genome Characterization Centres (GCCs) and Genome Sequencing Facilities (GSCs) for similar characterization and excessive-throughput sequencing. Then, series-associated facts are deposited inside the DCC. The Genome Characterization facilities also post hint documents, sequences, and alignment mappings to NCI's cancer Genomics Hub (CGHub) secure repository. The generated genomic records is made available to the research community and Genome Data Analysis Centers (GDACs). The GDACs provide new facts-processing, evaluation, and visualisation gear to the whole studies community to facilitate broader use of TCGA data. Furthermore, the statistics generated by means of the TCGA studies network is centrally managed on the DCC and deposited into public databases (TCGA Portal, NCBI's hint Archive, CGHub), allowing scientists to obtain cancer datasets.

TCGA applications

The Cancers Imaging Archive, TCIA (see "Relevant Websites section") TCIA is a service created through the NCI to host a huge range of medical images (radiological imaging statistics), from TCGA instances, therefore it supports imaging phenotype-genotype research. The data is de-identified and available for public download.

Berkeley Morphometric Visualisation and Quantification from H&E sections (see “Relevant Websites section”) is a data repository of computed histology-primarily based snap shots of various tumour samples from TCGA cases, and is backed via the Lawrence Berkeley National Laboratory.

The Cancer Digital Slide Archive (CDSA: see “Relevant Websites section”), is an online interactive device for viewing and annotating diagnostic and tissue slide photographs of different tumour kinds from TCGA assignment.

The Broad GDAC Firehose (see “Relevant Websites section”) is an analytical infrastructure created to coordinate the flow of cancers datasets, using various quantitative algorithms along with GISTIC, MutSig, Clustering, and Correlation.

The MD Anderson GDAC’s MBatch (see “Relevant Websites section”) is a website that permits scientists to discover and quantify the batch effects accompanying TCGA facts set, currently in line with hierarchical clustering and more desirable PCA plots.

Cancers Genome Workbench, (CGWB: see “Relevant Websites section”), is a utility evolved with the aid of the National Cancer Institute (NCI) to combine and display pattern-level genomic and transcription changes in numerous cancers, by obtaining information from several cancers projects, including TCGA. The major visitors in CGWB are incorporated tracks view, heat map view, and an alignment viewer known as Bambino.

Future perspectives of TCGA

Systematic advances in cancer genomics provided via TCGA have revealed a brand new approach of molecular biology in cancer. The application of high-throughput technology, boosted with bioinformatics analytics has been successful in highlighting the similarities and differences in the genomic structure of every cancer and across more than one kind. The TCGA has furnished a large amount of publicly available data on most cancers genetic and epigenetic profiles, highlighting candidate cancer biomarkers and drug objectives. Moreover, translation of cancer genomics into therapeutics and diagnostics will offer potential to increase personalized cancer medicinal drug. The ultimate goal for scientists is to develop very high end bioinformatics tools to get rid of noise in data and enhance the decision of the analysis, for cutting edge discoveries. In the future, all novel findings will facilitate diagnosis, treatment, and cancer prevention. Lately, researchers have new discoveries in cancer research by trying to “teach” a device – an artificially clever laptop, called Watson – to aid doctors in diagnosing patients. In time to come, these rapid advances can hopefully be incorporated into clinics (Tomczak *et al.*, 2015).

Results and Discussion

Results are presented in terms of database models, tools and architecture employed in developing biological databases.

Database Models

Predominantly, traditional relational model has been used in the design and development of biological databases. Some prominent example of relational databases are GenBank, EMBL, SWISS-PROT and Protein Information Resource(PIR) and CBS Genome Atlas Database.

However, with the recent development in the semantic web technologies, many biological ontologies have been created that uses object based database models using ontologies and nosql database tools. One good example is BioPortal (see “Relevant Websites section”) which is a repository for biomedical ontologies. It currently contains 704 ontologies. Other prominent examples are BioPAX (see “Relevant Websites section”), Cell Cycle Ontology (CCO: see “Relevant Websites section”), Gene Expression Knowledgebase (GexKB: see “Relevant Websites section”), Disease Ontology (see “Relevant Websites section”), Gene Ontology Consortium (see “Relevant Websites section”), Sequence Ontology (see “Relevant Websites section”) and SNOMED CT (see “Relevant Websites section”). A good example of ontology based database is the Fish Ontology (FISHO: see “Relevant Websites section”) which is shown in Fig. 12.

The Human Protein Reference Database (HPRD: see “Relevant Websites section”) (Prasad *et al.*, 2009), on the contrary, was developed using the traditional object based data model.

A summary of database models and development tools employed in biological databases are presented in Table 1.

Database Architecture

In terms of database architecture, all three approaches: Distributed, Federated and Data Warehouse have been utilised in biological databases. Example of distributed databases include Ensembl, WormBase, and the Berkeley Drosophila Genome Project whereas examples of federated databases are TwinNET (Muilu *et al.*, 2007), ENCODE (Blankenberg *et al.*, 2007), EBI search (Park *et al.*, 2017), SPINE2 (Goh *et al.*, 2003), Cancer Biomedical Informatics Grid (Saltz *et al.*, 2006), NIF (Gardner *et al.*, 2008), Biomedical Informatics Research Network (Ashish *et al.*, 2010), Biomedical Investigations (Taylor *et al.*, 2008), EdgeExpressDB (Severin *et al.*, 2009) and Minimal Information About Neural Electromagnetic Ontologies (Frishkoff *et al.*, 2011). Examples of biological databases that are built on data warehouse concept are Pathway Commons (Cerami *et al.*, 2010), String (Szklarczyk *et al.*, 2010), CBS Genome Atlas Database (Hallin and Ussery, 2004), BioMart (Haider *et al.*, 2009), BrainMap (see “Relevant Websites section”), PubBrain (see “Relevant Websites section”).

(2016). 2016 update of the PRIDE database and its related tools. <i>Nucleic Acids Research</i> , 44(Database issue), D447–D456. https://doi.org/10.1093/nar/gkv1145

some fraudulent parties. Scientists who may not want to share unpublished data have their valuable data stored in personal computers which are most of the time untapped. These kind of speckled data, both textual and image data, will not allow discovery of new knowledge and its evident that correlated data can give rise to new discoveries in science.

Finally, the development of databases require data to be in the digital form and digitizing biological data is a daunting task. It requires extensive manpower, enough equipments and all of these requires funds. However, this can be overcome if world class biological data centres makes databasing lenient enough for underprivileged scientists.

Future Directions

In line with the advancement of the digital world and high performance computing technology, biological databases have been mushrooming and the number is expected grow consistently. These biological databases have become an integral part of research in many scientific areas, from data extraction, knowledge discovery and biological simulations to advanced analysis.

In line with the exponential increase in size and heterogeneity of biological data, new database models have been proposed, which are more scalable compared to traditional relational databases deployed on single computer system. Recent studies by [Valduriez \(2011\)](#), [Han et al. \(2011\)](#) and [Konishetty et al. \(2012\)](#) have explored the practical implementations of NoSQL databases to help in developing a viable and usable practice in information management. While new biological databases are being introduced every year, it is now important to relook at models and infrastructure deployed in construction of these databases. Older database models such as relational, which have been the core technology behind biological databases, are losing its relevance with regards to handling exponential increase of data. Therefore, traditional database concepts are evolving in order to meet and map the data management requirements of today's environment.

The growing data in genomics, metabolomics, proteomics and metagenomics can be regarded as Big Data if these data sources are harmonised. It is critical to explore back end data integration that are streamlined into front end resilient computer systems for performing seamless transactions, whether for simple search algorithms or high level data science. In order to achieve this vision, these data sources need to be mediated via ontologies and noSQL databases by adopting parallel computing technology and artificial intelligence. In order to facilitate the new paradigm, automated methods need to map relational models (SQL based) into noSQL models which are the essence of big data applications.

NoSQL graph model has recently become very popular as it presents a solution to many of today's challenges such as visualisation of data with complex connections and rich relationships.

Closing Remarks

This article presents a holistic overview of biological databases, with regards to modeling and the architecture of the databases. A comprehensive literature on biological databases is presented with a focus on two case studies which are GeneCards and Cancer Genome Atlas. This literature, however, by no means covers the whole range of biological databases that are currently available. The Nucleic Acids Research Journal features the latest biological databases with a very good coverage on the most recent research in this area (see "Relevant Websites section"). Finally, the future direction of biological databases is discussed focusing on the new concepts in the digital world such as Big Data, Data Science and NoSQL databases which holds the future of biological databases.

Acknowledgement

I would like to thank all my postgraduate students for assisting in my biological database research over the years. The research contribution made by these students ranging from relational models, semantic web, ontologies, image databases, noSQL and graph models as well as medical databases has been overwhelming.

Introduction

Functional genomics is a branch that integrates molecular biology and cell biology studies, and deals with the whole structure, function and regulation of a gene in contrast to the gene-by-gene approach of classical molecular biology technique. It aims to relate the phenotype and genotype on genome level and includes processes such as transcription, translation, protein-protein interaction and epigenetic regulation. This involves comprehensive analysis to understand genes, their functional roles and variable levels of protein expression. The Human Genome Project (HGP) ([Collins et al., 2003](#); [Green et al., 2015](#)) is an integral part of functional genomics. It elucidated that the human genome contains 3164.7 million nucleotide bases with the total number of ~20,000 genes. The size of chromosomes is in between 47 and 250 Mb. Chromosome 1 has a maximum number of genes (5078) and the MT has fewest (37). Functional genomics is characterized by the following distinct research areas:

Genetic Interaction Mapping

Gene Interaction

Gene interactions occur when two or more allelic or non-allelic genes of same genotype influence the outcome of particular phenotypic characters. To understand the molecular basis of this complex biological phenomena, there is a need of genetic interaction mapping where the effects on one gene are modified by one or several other genes. Furthermore, systematic pairwise deletion of genes or inhibition of gene expression can be used to identify genes with related function, even if they do not interact physically. Genetic interaction is the set of functional association between genes. One such relationship is epistasis, which is the interaction of non-allelic genes where the effect of one gene is masked by another gene to result either in the suppression of the effect or they both combine to produce a new trait (character). Mapping genetic interactions by simultaneously perturbing pairs of genes, which report on how genes work together, provides a powerful tool for systematically defining gene function and pathways.

The complex etiology of most human diseases that cannot be explained by single nucleotide polymorphism (SNPs) is thought to be caused by combination of multiple genetic variations. By finding the (i) similarities in sequences, gene order and fusion events, (ii) common structural motifs, or (iii) resemblance in gene expression, the role of uncharacterized proteins can be deduced computationally. Furthermore in gene networks, based on the comparison of neighbors, functionality of related genes can be deciphered ([Schlitt et al., 2003](#)). The statistical epistasis (deviation from additivity in a mathematical model) enabled the identification of an array of different gene interactions that include aggravating or synergistic interactions ([Boucher and Jenna, 2013](#)).

Computational Tools for Gene-Gene Interactions

Till date, almost 100 computational tools are available for epistasis detection (see “Relevant Websites section”). Some of the prominent ones are: (i) BEAM (Bayesian Epistasis Association Mapping), which treats the disease-associated markers and their interactions via a bayesian partitioning model and computes the posterior probability that each marker set is related with the disease by employing Markov chain Monte Carlo ([Zhang and Liu, 2007](#)) (ii) TEAM (Tree-Based Epistasis Association Mapping), for fast detection of gene-gene interactions without ignoring any epistatic interaction in genome-wide association study (GWAS) of humans ([Zhang et al., 2010a](#)), (iii) BOOST (BOolean Operation-based Screening and Testing), a computationally and statistically powerful tool for the detection of unrevealed gene-gene interactions, which is the basis of many complex diseases ([Wan et al., 2010](#)), and (iv) TS-GSIS (Two Stage-Grouped Sure Independence Screening), for studying SNP-SNP interactions with/without marginal effects as well as making direct inference and easy interpretation on the biologically important genes ([Table 1](#); [Fang et al., 2017](#)).

Single Nucleotide Polymorphism

A single-nucleotide polymorphism (SNP) is a variation in a single nucleotide that occurs at a specific position in the genome. These genetic variations in different individuals are the cause of differences in human genomes and are at the forefront of many disease-gene association studies. Based on SNPs, there are many techniques [for instance, Restriction Fragment Length Polymorphism (RFLP)] used for determining suspected individuals of crime such as DNA fingerprinting. Microsatellites or simple sequence repeats (SSRs) and minisatellites are abundant in whole genome and show polymorphism at a high level. SSRs are

Table 1 Tools implicated in gene interaction mapping, SNP and gene regulation

distributed both in coding and non-coding DNA and are implicated in diverse biological functions. Protein coding SNPs can be further divided into synonymous and non-synonymous (nsSNPs); synonymous SNPs do not change the amino acid sequence while nsSNPs do.

Tools Implicated in Analysis of SNPs

Several computational tools for the analysis of SNPs have been developed (Table 1; for a more exhaustive list of tools see Karchin, 2009). The algorithm CHOISS (Choosing Optimal-Interval SNP Set) finds a set of SNP markers based on interval regularity (Lee and Kang, 2004). Subsequently, an informative SNP selection method for unphased genotype data based on multiple linear regression (MLR) was implemented in the software package MLR-tagging (He and Zelikovsky, 2006). A neural network-derived method, SNAP (screening for non-acceptable polymorphisms), has also been established that predicts functional effects of nsSNPs by incorporating evolutionary information (residue conservation within sequence families), aspects of protein structure (secondary structure, solvent accessibility) and other relevant information (Bromberg and Rost, 2007). kSNP3.0 is a program for SNP detection and phylogenetic analysis of genomes without genome alignment or reference genome (Gardner et al., 2015). Recently, a database SP2TFBS was developed that catalogs regulatory SNPs affecting predicted transcription factor binding site (TFBS) affinity (Kumar et al., 2017).

Gene Regulation

Promoter Analysis

There are two main promoters, one TATA-box enriched promoter, a well-defined binding site, and another CpG island promoter. Using the Cap Analysis of Gene Expression (CAGE) approach, it is possible to re-design promoter for differential gene expression. One can tag several thousand transcription start sites and quantitatively analyze promoter usage of different tissues with their differential expression in such sites. The identification and analysis of promoters is essential to understand the transcriptional regulatory networks. Several transcriptional start sites databases have been developed (**Table 1**), amongst which many are dedicated to eukaryotes and mammals for instance, DBTSS (Database of Transcription Start Sites), SCPD (*S. cerevisiae* Promoter Database) and microTSS (hosts miRNA transcription start sites). DBTSS covers the data of the majority of human adult and embryonic tissues, and contains 418 million TSS tag sequences from 28 different tissues/cell cultures (Wakaguri *et al.*, 2008). On the other hand, SCPD catalogs experimentally mapped TFBSs and TSSs in yeast *S. cerevisiae* (Zhu and Zhang, 1999). These databases not only identify and retrieve promoters but also provide information on genes with mapped regulatory regions.

Various Regulatory Regions

Different types of regulatory regions are present in our human genome sequence which is a huge source of data of functional genes (Collado-Vides *et al.*, 2009). Different expression of promoter depends on various factors like transcription factor, enhancer, activator, repressor and they define the regulatory region. In addition, there are conserved sequences in human genome that can be employed in phylogenetic footprinting; it is an area of bioinformatics used to identify TFBSs within a non-coding region of DNA by comparing it to the orthologous sequences in different species (Impey *et al.*, 2004; Lenhard *et al.*, 2003). JASPAR is a database for transcription binding factor profiles and it catalogs matrix-based nucleotide profiles describing the binding preference of transcription factors from multiple species (**Table 1**; Sandelin *et al.*, 2004). In a similar vein, TRANSFAC database maintains data on eukaryotic transcription factors, their experimentally proven binding sites, consensus binding sequences and regulated genes (Wingender *et al.*, 1996). Likewise, TRANSCOMP database also contains data on eukaryotic transcription factors experimentally proven to act together in a synergistic or antagonistic manner (Matys *et al.*, 2006). On the other hand, PRODORIC hosts data on environmental stimuli with *trans*-acting transcription factors, *cis*-acting promoter elements and regulon definition (Munch *et al.*, 2003). It includes graphical representations of operon, gene and promoter structures including regulator-binding sites, transactivational start sites and also provides supplemented data on regulatory proteins.

In the vast area of functional genomics, finding the TFBSs on a whole-genome level, is a formidable challenge for gene-regulation studies including, annotation of regulatory sites and interpreting gene regulatory networks. MATCH (Kel *et al.*, 2003), oPOSSUM (Ho Sui *et al.*, 2005) and ConTra (Broos *et al.*, 2011) are some of the notable tools used to find TFBSs.

Pattern Discovery

Pattern identification is another area of bioinformatics that analyzes expression pattern of genes as well as sequence patterns in DNA, RNA or proteins. Additionally, in bioinformatics analysis, feature selection technique (Saeys *et al.*, 2007), also plays an important role in extracting huge data from genomic sequences (Sandelin and Wasserman, 2004).

Bioinformatics Tools Used for Regulation of Genes

The availability of numerous genomic sequences and the huge genome-scale experimental data allows the use of computational techniques to investigate *cis*-acting sequences controlling transcriptional regulation. Various tools have been developed to find new sites for a given transcription factor based on a set of known sites (for instance, MyPatternFinder Sharma *et al.*, 2009) and Fuzznuc (emboss.sourceforge.net/apps/cvs/emboss/apps/fuzznuc.html) as well as to find unknown DNA binding motifs for unspecified transcription factors by searching the regions upstream of the translational start sites of a set of potentially coregulated genes (for instance, MEME Bailey *et al.*, 2009; Tavan *et al.*, 1990) and MoPP (Sharma *et al.*, 2009; **Table 1**). AlignACE is a computational tool that implements Gibbs sampling algorithm for identifying motifs that are present in a set of DNA sequences in *S. cerevisiae* (Hughes *et al.*, 2000).

Microarray Data Analysis

Implications of Microarrays in Functional Genomics

Rapid and systematic study of the expression of many genes can be analyzed by microarray technology. On the solid surface (silicon chip, nylon membrane or glass slide), thousands of tiny spots (oligonucleotides) are immobilized at defined positions. These known oligonucleotides act as probes and permit similarity analysis by binding with corresponding unknown samples via hybridization for the purpose of gene discovery and their function. Thus, microarrays facilitate the finding of absolutely novel and

unexpected functional roles of genes (Slonim and Yanai, 2009). Furthermore, it compares the expression pattern of genes in normal and diseased tissues. Identification of SNP in the related genes can be observed by using guide DNA. Such kind of detection helps in mutation analysis as genes may differ from each other by single nucleotide base. In addition, microarrays are also being employed in comparative genome hybridization that permits the detection of altered chromosomal copy number and these alterations can be measured by hybridizing fluorescently labeled DNA from a diseased specimen to the microarray plate.

Applications of Microarrays

DNA microarrays are useful in the identification of various diseases like cancer, in the field of pharmacogenomics, in the discovery of drugs or development of more effective drugs for specific treatment strategies. Comparative study of biochemical composition of the gene product that is responsible for the disease with the proteins formed by the normal genes, helps researchers to synthesize drugs that can minimize the effect of such defective proteins. DNA microarrays help in gene discovery, their expression profiling, their regulation, genetic disease screening, SNP discrimination, microbial detection and typing, and observe variation between transcript levels of genes under different conditions. It also helps in toxicological research by tracking the modifications in the genetic profiles of the cells when exposed to certain toxicants. Additionally, microarray technology is useful in clinical microbiology as it is a potential tool for bacterial recognition and for diagnosis of bloodstream infections caused by certain pathogens. Another application of microarray technique is the determination of antimicrobial drug resistance by detecting the mutations due to drug resistance in the genome of microbes (Miller and Tang, 2009).

Computational Prospective for Microarray Technology

Various bioinformatics tools and programs are available for microarray data analysis and mining (Selvaraj and Natarajan, 2011). Computational analysis of microarray data becomes more important to address the problems of data quality, to handle the large amount of microarray data and standardization of this technology. For this, data mining needs to be carried out which includes clustering and classification. Clustering, as name suggests, is to categorize data into groups of related genes (genes with similar characteristics falls into single group). It is an unsupervised learning approach of classifying data into clusters of related observations and is based on the algorithm of K-means clustering and Self-Organizing Map (SOM) (Tavan *et al.*, 1990). On the other hand, classification is a supervised learning approach which predicts the class of the unknown gene by observing the pre-classified examples and is based on the algorithm such as Artificial Neural Network (ANN), k-Nearest Neighbors (kNN) and Support Vector Machines (SVM). One of the main application of classification is the prediction of disease type. Prominent tools available for the clustering analysis include MAGIC Tools (Heyer *et al.*, 2005) and dChip (Amin *et al.*, 2011) and for classification purpose include LIBSVM (see "Relevant Websites section") (Table 2).

High-Throughput GoMiner provides outcomes across multiple microarrays one at a time, for the broad scale of applications such as various drug treatments, time-courses evaluation, collective gene comparison (Zeeberg *et al.*, 2005). It organizes the list of under- and over-expressed genes, particularly those genes that have some biological importance in Gene Ontology. iArray (Simon *et al.*, 2007), EDGE (Leek *et al.*, 2006) and Cyber-T (Kayala and Baldi, 2012) are some of the programs available for gene expression analysis. Such studies are important for finding potential drug targets and biomarkers.

SAGE (Serial Analysis of Gene Expression)

Unlike microarray technology, where hybridization is the principle for analysing expression of genes, SAGE depends on RNA sequencing for global analysis of gene expression in a cell. The main benefit of using this technique over others is that it does not require any prior understanding of transcripts and it provides a clear illustration of both qualitative study by comparing gene expression between samples and quantitative study by identifying novel transcripts. The method involves the isolation of short (9–11 base pairs) oligonucleotides sequence tag from discrete mRNAs. These short distinctive sequence tags (SAGE tags) are unique to each gene, allowed to concatenate for efficient sequencing and analysis of transcripts in a serial fashion. The resulting sequence data are analyzed to identify each gene expressed in cell and the level of gene expression. This information can further be used to test the differences in the level of expression of gene between cells.

SAGE Bioinformatics Packages

The role of SAGE tools is very clear as we need them for the isolation of the unique sequence tags from raw sequence files and their tabulation as well as comparison of SAGE tag abundance. Furthermore, SAGE software helps in matching tags to reference sequences in other databases.

Various bioinformatics methods have been developed for compiling and analysing the SAGE data (Table 2; for a detailed list of tools see Tuteja and Tuteja, 2004). In order to identify the SAGE tags, SAGE300 (see "Relevant Websites section") compiles the database of tags extracted from human sequences in Genbank. In contrast, POWER_SAGE software is a useful tool for planning SAGE experiments and it has the capability of handling large number of transcripts/cDNAs and different sample size combinations

(Man *et al.*, 2000). Expression Profile Viewer (ExProView) is a tool for the analysis of gene expression profiles derived from expressed sequence tags and SAGE (Larsson *et al.*, 2000). It visualizes the transcript data in a two-dimensional array of dots, in which each dot represents a known gene as specified in the transcript database. In addition, SAGENet (see “Relevant Websites section”) catalogs tags for colon cancer, pancreatic cancer and corresponding normal tissues while SAGEmap is a public database for gene expression (Lash *et al.*, 2000).

Mutations

A mutation is an alteration in the primary sequence of a gene. Mutations may lead to an alteration in the structural and/or functional properties of proteins and result in some of the deadly diseases. Mutations can be categorized into two types (i) spontaneous and (ii) induced mutation. The spontaneous mutations involve deamination, depurination, tautomerism and slipped strand mispairing (Drake *et al.*, 1998). On the other hand, induced mutations occur due to the effects induced by chemicals such as hydroxylamine,

oxidative radicals, DNA intercalating agents (e.g., ethidium bromide), alkylating agents, base analogs and nitrous acid. Some other physical factors that have been known to induce mutations include ultraviolet light, ionizing radiation and DNA crosslinkers. The scale of mutations may be small or large, and may alter function of some of the essential proteins. Mutations may be classified as (i) Insertions (addition of DNA bases); (ii) Deletions (deletion of DNA bases); (iii) Duplications (a DNA segment is copied one or more times); (iv) Frameshift mutations (addition/loss of bases that shifts the reading frame of the codons); (v) Nonsense mutations (a sense codon changes to a premature stop codon that results in shorter, unfinished proteins); and (vi) Missense mutations (nucleotide substitutions that result in a different codon which codes for different amino acid). Even small mutations could lead to a defective phenotype. However, such unexpected consequences due to mutations are normally kept in check by an error-prone repair system of our highly developed replication system.

Mutation studies have been applied in pharmacological investigations for carrying out translational work in functional genomics. Mutations in a specific gene are detected using TILLING and AMES tests. With the advent of advanced bioinformatics techniques, it has been possible to analyze the mutations in various diseases like colon cancer and thus indicating a positive role of microsatellites in mutagenesis (Brinkmann *et al.*, 1998). Hereditary nonpolyposis colorectal cancer (HNPCC) is thought to increase the risk of developing colon cancer. Bioinformatics approaches have been employed to investigate the role of nsSNPs in HNPCC genes, by identifying functional SNPs and by exploring phenotypic variation due to genetic mutations (Doss and Sethumadhavan, 2009). These bioinformatic investigations have led to the study of various HNPCC related genes, pathways, diseases and post-translational modifications.

Bioinformatics in Mutational Studies

In recent years, bioinformatics studies have provided a new direction in mutational studies. Monte Carlo simulation methods deal with stochastic models in biology that are interactable mathematically. These methods have been used in the incorporation of mutation and natural selection into Wright-Fisher gametic sampling model (Mode and Gallop, 2008). It helps to predict an infinite model of various mutations, gene conversions, migration among subpopulations and allows recombination. In addition, Human Gene Mutation Database (HGMD) is a collection of germline mutations associated with human inherited diseases that contains 141,000 different lesions detected in over 5700 different genes, with new mutation entries (Table 2; Stenson *et al.*, 2014).

In vitro mutational study is a difficult and time taking process. However, the structural and functional study of mutational genes are possible through computational tools. For instance, there are various software tools available for driver mutation prioritization (see "Relevant Websites section"). The most notable tools among them are mentioned in this section (Table 2). The effects of missense mutations on the structure of a protein product can be analyzed even if its 3D (3 dimensional) structure is not available. The 3D structure of a protein can be deduced by using the primary sequence through homology modeling or other approaches like threading. The analysis of the effects of mutations on the structural stability of a protein can also be carried out. Investigations of steric, anomeric carbon, chiral center and stereochemical consequences of substitutions, provide insights on the molecular fit using structural studies. ProDrg (van Aalten *et al.*, 1996) and PyMOL (Lill and Danielson, 2011) are tools used to observe the effects of mutations on the 3D structure and also assist in carrying out computer-aided drug designing. The effects of missense mutations have been analyzed on the structure and function of p53, a tumor suppressor gene (Kato *et al.*, 2003). CRISPR (Type II Clustered Regularly Interspaced Short Palindromic Repeats)/Cas system helps in adaptive immune response by protecting the host cells against pathogens. Cas-OFFinder algorithm has been developed to search for potential off-target sites in a given genome or user-defined sequences (Bae *et al.*, 2014).

Over 4 million coding mutations have been identified across all human cancer disease types. COSMIC (Catalogue Of Somatic Mutations In Cancer database) describes 10 million non-coding mutations, 1 million copy-number aberrations, 9 million gene-expression variants, and almost 8 million differentially methylated CpGs (Bamford *et al.*, 2004). Mutated protein sequence analysis can also lead to evolutionary relationships. Evolutionary trees are constructed for prediction of orthologs, xenologs and paralogs using Hidden Markov Model (HMM) algorithm. PANTHER (Protein ANALYSIS THrough Evolutionary Relationships) provides a single nucleotide polymorphism (SNP) scoring tool that uses multiple sequence alignments to identify amino acid substitutions (Mi *et al.*, 2016). Similarly, SIFT (Sorting Intolerant From Tolerant) predicts the occurrence of non-synonymous polymorphisms or laboratory-induced missense mutations based on PSI-BLAST (Ng and Henikoff, 2003). On the other hand, Mudi identifies the causative mutations in the whole-genome sequence data and performs mapping, annotation, prioritization and detection of variant alleles (Iida *et al.*, 2014).

Cancer is caused by DNA sequence abnormalities. A major challenge in cancer is to detect a defected gene via somatic mutation profiling. The Cancer Genome Atlas [TCGA] (Cancer Genome Atlas Research *et al.*, 2013) and the International Cancer Consortium [ICGC] (Zhang *et al.*, 2011) are two comprehensive and coordinated projects that deal with systematic profiling of genome alterations in many cancer types. MUFFINN (Mutations for Functional Impact on Network Neighbors) introduced an intuitive, frequency-based approach to quantify the significance of the mutation frequency of each gene or a genomic region compared with a background mutation rate [BMR] (Cho *et al.*, 2016). MUFFINN prioritizes genes based on four ways: (i) the mutation frequency of each gene as well as that of its neighbors in a functional network; (ii) mutation frequency of direct neighbor genes of maximum mutation frequency; (iii) mutation frequency of all direct neighbors with normalization by the number of their network neighbors; and (iv) mutational frequency of all genes of the entire network with diffused weight through the network. On the other hand, Polyphen-2 is a tool implemented in R language to predict the

adverse effects of a missense mutation on the protein stability. It uses eight sequence-based and three structure-based predictive features, which are selected automatically by an iterative greedy algorithm (Adzhubei *et al.*, 2013). The prediction pipeline is characterized by comparing two properties like wild-type allele (normal) corresponding to mutant allele (disease). Likewise, PROVEAN webserver also predicts functional effects of amino acid substitution using alignment-based approach (Choi and Chan, 2015).

miRNAs/Transposons

Genomics, Biogenesis and Mechanism of Regulatory RNA

MicroRNAs (miRNAs) are approximately 22 nucleotides long double stranded endogenous non-coding RNAs. miRNAs play an important role in the suppression of target mRNAs (Krol *et al.*, 2010). For instance, Lin-4 is the predominant regulatory RNA that controls the larval development in *C. elegans*. It is now recognized as the founding member of a large class of miRNAs (Bracht *et al.*, 2010). Two RNase III enzymes, named as DORSHA and DICER, cleave primary mRNA and hence, release a hairpin loop in the nucleus (Han *et al.*, 2004). This mRNA is then exported to cytoplasm and cleaved by DICER that results in mature miRNA duplex. The resulted mature miRNA duplex again gets processed by DICER protein and finally two strands act as guide RNA and passenger RNA. The function of guide RNA strand is to cleave the target mRNA specifically, in order to repress its function. On the other hand, passenger mRNA strand acts as an helper for guide RNA to specifically bind to the target mRNA. The pathway of short-interfering RNA (siRNA) or silencing RNA is similar to miRNA, except that the maturation of siRNA is in the cytosol rather than in the nucleus (Bartel, 2004; He and Hannon, 2004).

Computational Approaches for Studying miRNAs

Experimentally, the functional study of miRNA is a time-consuming process. Hence, various computational approaches have been developed for the study of orthologous and paralogous gene identification of miRNAs. Furthermore, several bioinformatics tools have been developed to manage the exponential growth in the generation of miRNA-related data. The main goals of currently available tools are (i) miRNA expression analysis, (ii) miRNA target prediction, (iii) miRNA detection, (iv) studying miRNA in the

context of metabolic and signaling pathways, (v) analysis of interplay between miRNA and transcription factors, (vi) study miRNA in therapeutics, and (vii) identification of miRNA regulatory networks (Akhtar *et al.*, 2016). Here, we discuss some of the major bioinformatics resources and tools that deal with these aspects of miRNA research. High throughput sequencing of mRNA is possible through RNA sequencing. On the basis of small-RNAseq data and expression values, several databases such as miRbase, miRDB, microRNA.org, YM500, DASHR and deepBase have been developed (Table 3). These databases help to predict the functional annotations, target predictions and expression profiles of various miRNAs.

miRBase is an online repository of miRNA sequences and annotations (Griffiths-Jones *et al.*, 2008). It has more than 28,645 entries representing hairpin miRNAs that expressed 35,828 mature miRNA products in 223 different species (Moore *et al.*, 2015). The sequence data, nomenclature, annotations and target predictions have been mentioned systematically. In a similar vein, miRDB is a resource for miRNA target predictions and functional annotations, which are known to play a crucial role in understanding various physiological and disease processes (Wong and Wang, 2015). Till date, it has 2588 and 1912 functional miRNAs from humans and mice, respectively. For better prediction of targets, Support Vector Machine (SVM) has been incorporated as MirTarget algorithm in this resource. Likewise, microRNA.org predicts candidate targets using miRanda algorithm and hosts expression profiles to provide functional information. The current version of the database has target sites for 1100 human, 717 mouse, 387 rat, 186 *D. melanogaster*, and 233 *C. elegans* miRNAs. In comparison, YM500 database has about 11,000 cancer-related smRNA and 10,000 RNA-seq datasets (Cheng *et al.*, 2013). It allows visualization of expression data, enables search for existing evidence of the novel miRNAs, analyzes arm switching phenomenon, performs survival analysis of a specific small non-coding RNA (sncRNA) in different cancer types and finds the isomiRs of the known miRNAs in miRBase. DASHR (Database of small human non-coding RNAs) is another repository for human sncRNA genes, precursor and mature sncRNA annotations, sequence, expression levels (Leung *et al.*, 2016). Currently, it stores 187 small-RNA deep sequencing datasets from 42 tissues and cell types for more than 48,000 sncRNA loci, genes and mature sncRNA products. DASHR allows searches using sncRNA gene name or RNA sequence, location of sncRNA loci in a given interval of genomic coordinates, and visualization of expression of sncRNA genes and mature products.

miRmine is a human miRNA expression database developed using 304 high-quality microRNA sequencing (miRNA-seq) datasets from NCBI-SRA (Panwar *et al.*, 2017). The expression profiles for one or more miRNAs from a specific tissue or cell-line, either normal or with disease information can be retrieved easily. In addition, miRsig (miRNA signature) is a web tool developed for prediction and visualization of the common signatures or core sets of miRNA-miRNA interactions for different diseases (Nalluri *et al.*, 2017). It uses six network inference algorithms, generates scores using each of the algorithms and generates disease-specific miRNA-interaction networks using a consensus-based approach. Finally, it makes the graph intersection analysis on multiple diseases to find core interactions. Amongst siRNA (small interfering RNA) based research studies, siDirect has been developed for computing functional and off-target minimized siRNA design for mammalian RNA interference (RNAi). The server accepts an input sequence and returns siRNA candidates that can be used for systematic functional genomics and therapeutic gene silencing (Ui-Tei *et al.*, 2004). Another distinct tool MatureBayes has been established that uses a machine learning approach for the prediction of miRNA genes products (Gkirtzou *et al.*, 2010). It employs Naive Bayes classifier and uses sequence and secondary structural information of miRNA precursors to determine mature miRNA candidates. It can predict the start position of mature miRNA using information from miRNA precursors in humans and mouse. BUFET (Bitset-based Unbiased miRNA Functional Enrichment Tool) is a recent and novel computational approach that helps to discover potential biological functions that would be affected by the differential expression of a group of miRNAs (Zagganas *et al.*, 2017). It implements efficient data structures that lead to a significant reduction in the execution time of the unbiased enrichment analysis. In addition, this tool exploits parallel architecture of multi-core systems to increase its performance.

Plant miRNAs

The plant miRNAs are non-coding regulatory RNAs that perform important roles in the regulation of plant development and physiological processes like growth, development and stress responses. Plant miRNAs have also played a significant role in the phenotypic evolution, for instance, adaptation of plants to life on land (Taylor *et al.*, 2014). Till date, 20 unique *Arabidopsis* miRNAs have been reported; a few are closely related to each other representing 15 distinct miRNA families. Since some could be derived from multiple genomic loci, the 20 miRNAs could represent more than 40 *Arabidopsis* genes (Bartel, 2004).

In both plants and animals, miRNAs regulate the expression of the target mRNA, often in the context of regulating developmental events. However, in spite of similarities between them, the repression mechanism of target mRNAs varies between plants and animals. Repression of gene expression in animals is mediated by translational attenuation of 3' UTRs (untranslated regions) of target mRNAs that contains multiple miRNA binding sites. Whereas, in almost all plants, miRNAs regulate the gene expression of their target mRNAs by cleaving at a single site within the coding region (Millar and Waterhouse, 2005). Besides their roles in growth, development and maintenance of genome integrity, sncRNAs are also important components in plant stress responses (Khraiwesh *et al.*, 2012). The expression profiles of most miRNAs involved in plant growth and development are significantly altered during stress (Sunkar *et al.*, 2012). miRNAs in different plant species are modulated differently in abiotic and biotic stresses. Furthermore, miRNA398 (miR398) has been proposed to regulate plant stress responses due to oxidative stress, water deficit, salt stress, abscisic acid stress and ultraviolet stress (Zhu *et al.*, 2011).

A critical step in elucidating miRNA function is identifying potential miRNA target. Target-align is one such prediction tool which uses dynamic programming alignment techniques (Table 3; Xie and Zhang, 2010). Trans-acting siRNAs (ta-siRNAs) play a significant role in regulating gene networks involved in development, metabolism, DNA methylation and stress responses. TasiRNAdb is a

database developed for a comprehensive understanding of ta-siRNA regulatory pathways in plants (Zhang *et al.*, 2014). This database also provides a tool, TasExpAnalysis, for mapping user-submitted RNA and degradome libraries to a ta-siRNAs-producing locus (TAS). In addition, the users can perform TAS cleavage analysis and sRNA phasing analysis within tasiRNAdb. Concurrently, a distinct tool miR-PREFeR (miRNA PREdiction From small RNA-Seq data) has also been developed that uses the expression profiles of miRNAs from small RNA-Seq data samples, for the precise prediction of plant miRNAs (Lei and Sun, 2014).

miRNA in Therapeutics

By regulating gene expression, miRNAs play an important role in various biological processes like cell proliferation, apoptosis, biogenesis, transcription and signal transduction. It is not surprising that the deregulation of miRNA results in many human diseases. This can be illustrated by some examples: (i) miRNA expression pattern in heart disease shows that miR-1, miR-29, miR-30, miR-133, and miR-150 have often been found to be down-regulated while miR-21, miR-125, miR-195, miR-199, and miR-214 are up-regulated with hypertrophy (Shah *et al.*, 2009); (ii) miR-17-92 is overexpressed in lung cancer (Hayashita *et al.*, 2005), and (iii) let-7 has been found to be a suppressor miRNA in tumor cells (Johnson *et al.*, 2005).

The recent advances in application of antisense RNAi (RNA interference) and mRNAs has made it possible to manipulate miRNA regulations and hence show considerable promise as therapeutic agents (Vidal *et al.*, 2005). Decreased level of miR-122 in hepatitis B virus (Jopling *et al.*, 2008), miR-21 upregulation in hepatocellular carcinoma (Xu *et al.*, 2011) and high expression of miR-10b in glioblastoma (Gueussous *et al.*, 2013) are few signatures associated with their respective diseases. Dysregulated miRNAs have been observed in cancer therefore miRNAs have also been used as biomarkers for cancer diagnosis. miRNA studies have great potential in terms of drug discoveries due to their involvement in different biological pathways. Recently, clinical trials have been carried out for miRNAs- and siRNAs-targeted therapeutics (Rupaimoole and Slack, 2017). The *in silico* approaches and potential use of bioinformatics to predict miRNAs and their targets has seen a lot of development especially in the context of diseases (Tombol *et al.*, 2009; Banwait and Bastola, 2015).

Transposons in Functional Genomics

Transposable elements or jumping genes are moderately repeated mobile DNA sequences, interspersed throughout the genomes. These elements are of two types, retrotransposons (type I elements) and transposons (type II elements). They regulate the functioning of a gene and the evolution of genome. Transposase enzyme helps in the mobilization of transposons. Generally eukaryotes contain retrotransposons, but plants have transposons in their genome. Retrotransposons follow a copy and paste mechanism *i.e.*, first DNA is copied to a RNA molecule that is reverse transcribed again into a DNA using the reverse transcriptase enzyme. This reverse transcribed DNA sequence is then inserted at new position into the genome. In contrast, transposons follow cut and paste mechanism that do not involve any RNA intermediate. They can bind to target site in both specific or non-specific manner. Retrotransposons are of two types LTRs (long terminal repeats) and Non-LTRs (non-long terminal repeats). The most abundant Non-LTRs present in mammals are of two types, LINEs (long interspersed nuclear elements) and SINEs (short interspersed nuclear elements). Multiple copies of transgenes and transposons are often integrated within the genome and they are considered to be identical as endogenous sequences. Repetitive sequences and their transposition is very important in the context of therapeutic studies of diseases, like cancer. Several bioinformatics approaches have been developed to understand various aspects of these elements (Table 3). Repbase is a database for transposable elements (TEs) and other types of repeats from eukaryotic genomes (Bao *et al.*, 2015). The current version of the database contains 38,000 sequences of different families or subfamilies of repeats. In addition, RetroSeq is a tool that can be used for the prediction and genotyping of non-reference transposable element (TE) insertions from whole genome sequencing data (Keane *et al.*, 2013). On the other hand, SRF (Spectral Repeat Finder) is a widely used tool for the detection of all the types/classes of repeats, including transposons, within genomic DNA (Sharma *et al.*, 2004).

Epigenomics

Epigenomics (*i.e.*, genome science of epigenetics) provides the functional context of genome sequences and proposes that organization of genes in a particular order on a chromosome and arrangement of these chromosomes in a cell play an important role in deciphering the function of genes. Epigenetics encompasses heritable changes in the DNA structure without changing the genetic code, *i.e.*, change in phenotype without any change in genotype, resulting in chromatin remodeling and consequently affecting transcriptional potential and expression of genes. This is a natural process that takes place regularly in the cell/s of an organism. Epigenetics plays a crucial role in different cellular events, for instance, cell development and differentiation. Several factors, like environment, age, and disease states, may have disruptive effects on a gene's expression pattern. It has been shown that the epigenetic states such as gene silencing can be induced by processes like DNA methylation or by expression of non-coding RNA (Egger *et al.*, 2004; Schubeler, 2015).

Functional anatomy of genome, provided by epigenomics has disclosed various connections among genes and with the nearby non-genic DNA. One such example is beta-globin cluster of human hemoglobin, in which genes are distinctively expressed

throughout the development (Proudfoot *et al.*, 1980). During the development stages of cluster, the genes are arranged in order of their expressions. Another astonishing interaction is found between intra- and inter-chromosomes, mediated by chromatin proteins (van Steensel and Dekker, 2010). In fact, DNA loop structures were also found to be associated with functions that can be illustrated by multiple interleukin genes in Th2 cytokine locus of mouse (Cai *et al.*, 2006). An example of large-scale genomic organization mediated by chromatin is the link between long RNAs, heterochromatin modification and gene activity (Feinberg, 2010). Furthermore, the organization of genome is affected by Large Organized Chromatin K9-modifications (LOCKS) and these large regions provide a vital mechanism for functional genomic organization (Wen *et al.*, 2009).

Epigenetic diseases such as cancer, play an important role in epigenetic pathology. The combination of mutations, structural variations and epigenetic alterations differ between each tumor, making patient-specific diagnosis and treatment strategies necessary (Schweiger *et al.*, 2013). Epigenetic modifications play a critical role in the regulation of transcription, DNA repair and replication. The cause of a disease may be due to the environmentally driven variation in epigenetics, particularly as a substitute for mutational change (Jiang *et al.*, 2004). The risk of a disease might also be due to (i) chromatin remodeling or post transcriptional

Table 4 Tools and databases used in epigenetics

Website	Key feature(s)	CI ^a	Access ^b	URL
4D Genome	Resources of chromatin interaction for structure and function relationship of genome	24.0	W	https://4dgenome.research.chop.edu

modification of histones (e.g., acetylation, ubiquitinylation or methylation), (ii) binding factors, and (iii) DNA replication, repair and transcription based processes (Dawson and Kouzarides, 2012). The database PathoYeasttract (PATHOgenic YEAsT Search for Translational Regulators and Consensus Tracking) helps in the prediction of the regulatory associations in pathogenic yeasts *Candida albicans* and *C. glabrata* (Table 4; Monteiro *et al.*, 2017). High throughput sequencing technologies provide the comprehensive maps of nucleosome positioning and chromatin conformation (de Wit and de Laat, 2012). In addition, epigenomics is transforming the search for genetic causes of common human diseases on the basis of epigenome anatomy with relevant possible disease list and a new approach to their search (Feinberg, 2010).

During the cell division, DNA exists in highly condensed thread-like structures called chromosomes. The DNA in a eukaryotic chromosome is traditionally bound by two classes of proteins called histones and non-histone proteins. Histones (namely H1, H2A, H2B, H3, H4) are responsible for the most basic level of chromosome organization termed as nucleosomes. Nucleosome exists in a fully super condensed form with the help of histone proteins. However, the histone proteins can be chemically modified during the process of replication and transcription by acetylation, methylation, phosphorylation, sumoylation, ubiquitylation and ADP ribosylation process. These chemical modifications of histones lead to chromosomal rearrangement and consequently help in the regulation of gene expression. Such alterations in DNA organization do not change DNA sequences but still change the expression pattern of a gene and possibly the phenotype of an organism.

DNA Methylation, Genome Imprinting and Paramutation

In mammals, 70%–80% of the cytosines have to be methylated to form 5-methylcytosine within a gene, thereby altering the gene expression. Occasionally, some genes remain unmethylated, for instance, Toll-like receptors in dendritic cells, monocytes and natural killer cells. Various studies have been carried out to decipher how CpG islands remain methylation-free in a globally methylated genome (Deaton and Bird, 2011). Interestingly, in cancer cells, CpG islands are known to contribute to gene silencing. The method BsRADseq (bisulfite-converted restriction site associated DNA sequencing) has the ability to quantify the level of DNA methylation differentiation across multiple individuals (Trucchi *et al.*, 2016). The epigenetic phenomenon that causes genes to be expressed in a parent-of-origin specific manner in daughter cells is termed as ‘genome imprinting’. The expression or suppression of genes in progeny is determined by an epigenetic factor of the parental genome. Indeed, the epigenetic mechanisms that are involved in genomic imprinting and X chromosome inactivation (Barr body) share marked similarities. The imprinted genome of various species are listed in Gene Imprint database (See Relevant Websites Section) (Table 4). In comparison, the Catalogue of Imprinted Genes is a collation of genes and phenotypes for which parent-of-origin effects have been reported (Morison *et al.*, 2001). WAMIDEX (Web Atlas of Murine genomic Imprinting and Differential EXpression) is another useful tool that integrates murine imprinted genes with a genome browser that makes microarray data easily accessible in annotation rich genomic context (Schulz *et al.*, 2008).

Sometimes changes in one allele induce the heritable changes in other allele, for example, the color of corn kernels in maize. This phenomenon is called paramutation. Gene expression is regulated by two ways - *cis* or *trans*. In *cis*-interactions, the binding site is on the same molecule of DNA as the gene(s) to be transcribed, while for *trans*-interactions it is on the other DNA molecule or chromosome. In *trans* interactions, paramutation occurs between homologous DNA sequences on different chromosomes that lead to changes in gene expression that are transmitted to next generation through mitosis and meiosis. Paramutation has been observed mainly between homologous DNA sequences present in both allelic and non-allelic positions.

Computational Tools in Epigenetics

The Nucleic acid builder (NAB) is a molecular mechanics program which is used for generation of three-dimensional molecular structures, for instance, in the library in DNA wrapping study (Table 4; Cheatham *et al.*, 2001). Flexibility is one of the factors involved in DNA binding to nucleosomes, and the salt concentration and DNA sequence affects this flexibility. The NAB package provides an alternative to molecular dynamics in implicit solvent and can be used to produce a picture of the vibrational motions for small nucleic acids. DNA duplexes are usually long due to which they have different open and closed curves. The NAB library can be used to produce simple closed circles with or without supercoiled form, simple nucleosome core fragment model and duplex winding around any open curve. Furthermore, various tools and databases have been associated with methylation, CpG islands, histones and chromatin structures (Table 4).

DNA methylation databases

As discussed above, DNA methylation has an important role in epigenetics. The first database developed was MethDB which provides information about DNA methylation profiles and associated gene expression (Amoreira *et al.*, 2003). The database contains experimentally compiled data of a DNA, where cytosine is converted into 5-methylcytosine through methylation process and then regulates epigenetic process in different genes, cells and tissues. It mainly describes methylation profile, pattern and content. The methylation profile gives positional values of cytosine in a sequence of interests. Subsequently, NGSmethDB and MethBase that are based on DNA methylation in bisulfite sequencing data were developed. NGSmethDB retrieves methylation data derived from next-generation sequencing. Two cytosine methylation contexts (CpG and CAG/CTG) are considered. Through a browser interface, the user can search for methylation states and retrieve methylation values for a set of tissues in a given chromosomal region, or display the methylation of promoters among different tissues (Hackenberg *et al.*, 2011). Whereas, MethBase (a database of annotated

methyomes from the public domain) along with MethPipe (a pipeline for both low and high-level methylome analysis) enable researchers to extract interesting features from methylomes and compare them with those identified in public methylomes (Song *et al.*, 2013). MethylomeDB is the first comprehensive source methylation profile of brain that facilitates the comparative epigenomic investigation, as well as analysis of schizophrenia, Alzheimer disease and depression methylomes (Xin *et al.*, 2012). On the other hand, MethBank is another DNA methylome programming database dedicated to storing, browsing and visualizing the genome-wide single-base nucleotide methylomes of gametes and early embryos at different developmental stages in mouse and zebrafish (Zou *et al.*, 2015). In contrast to other methylation databases, MethSMRT is the first database hosting 6-mA and 4-mC methylations (Ye *et al.*, 2017). Additionally, Epigenetic Module based on Differential Networks (EMDN) algorithm was developed for simultaneous analysis of DNA methylation and gene expression data (Ma *et al.*, 2017). Quantitative Sequence Enrichment Analysis (QSEA) is a comprehensive workflow for predicting exact levels of DNA methylation from sequence enrichment experiments (Lienhard *et al.*, 2017). Since aberrant changes in DNA methylation leads to diseases, DiseaseMeth, a repository for DNA methylation in human diseases, was established (Xiong *et al.*, 2017).

CpG island related databases

DBCAT (database of CpG islands and analytical tools) is a database for investigating comprehensive methylation profiles of DNA in human cancers. The database contains information regarding the human genes and CpG islands while the analytical tools comprise of a CpG island finder, a genome query browser and a methylation microarray analytical tool. The analytical tool identifies genes with methylated regions, provides comparison across microarrays and also displays the information about probe sites, intensities, and transcription binding sites. It is the first methylation analytical tool investigating epigenetic regulation related to a human disease (Kuo *et al.*, 2011). CpGProD (CpG island Promoter Detection) is another tool for identifying CpG island associated with transcription start sites in mammalian genome sequences (Ponger and Mouchiroud, 2002). In contrast, CpGcluster is based on the physical distance between neighboring CpGs on the chromosome and is able to predict directly clusters of CpGs. By assigning a p-value to each of these clusters, the most statistically significant ones are predicted as CpG islands (Hackenberg *et al.*, 2006). Recently, machine learning methods have also been incorporated in this field. The neural networks based DeepCpG method has been formulated to predict methylation states in single cells (Angermueller *et al.*, 2017).

Histone related databases

HistoneDB is a resource for the interactive comparative analysis of histone protein sequences and their implications for chromatin function (Draizen *et al.*, 2016). Over the past decade, several enzymes that catalyze and modify histones have been discovered, enabling investigations of their roles in normal cellular processes and adverse pathological conditions. Histone (The Histone Infobase) is a browsable, manually curated and relational database of 55 human histone proteins, 106 distinct sites of their post-translational modifications and 152 histone-modifying enzymes (Khare *et al.*, 2012). In addition, Human Histone Modification Database (HHMD) focuses on storage of histone modification datasets that can be searched for functional annotations, gene ID, chromosome location and cancer name (Zhang *et al.*, 2010b). EpiFactors, is a curated information-based database to facilitate epigenetic regulators, their complexes, targets and products. EpiFactors contains information on 815 proteins, including 95 histones and protamines, as well as 69 protein complexes that are involved in epigenetic regulation (Medvedeva *et al.*, 2015).

Chromatin related databases

DNA is wrapped around histone proteins to form highly condensed chromatin structure in order to fit into the nucleus of a cell. Post-translational modifications of histone proteins play an important role in gene expression. ChromatinDB is a database for histone modification of *Saccharomyces cerevisiae* (O'Connor and Wyrick, 2007). On the other hand, 4DGenome is a distinct database that hosts chromatin interaction data from five organisms and covers all experimental/computational technologies for detecting chromatin interactions including 3C, 4C-Seq, 5C, ChIA-PET, Hi-C, Capture-C and IM-PET (Teng *et al.*, 2015). In addition, CR Cistrome is an online resource for the linkage of chromatin regulators with histone modifications and datasets collected from ChIP-sequencing (Wang *et al.*, 2014).

General Tools Implicated in Functional Genomics

The Database for Annotation, Visualization and Integrated Discovery (DAVID) is a widely used tool that allows functional classification of genes, discovers functionally related genes, enables conversion of gene/protein identifiers from one type to another as well as explores gene names in a batch (Huang *et al.*, 2007; Dennis *et al.*, 2003; Table 2). On the other hand, GSEA (Gene Set Enrichment Analysis) is Gene Ontology based functional enrichment analysis method that recognizes the over-expressed and statistically significant set of genes or proteins among large set of data (Hung *et al.*, 2012; Subramanian *et al.*, 2005). In addition, a protein Complex Enrichment Analysis Tool (COMPLEAT) has also been developed for analysing high-throughput data, particularly for analysis of network dynamics (Vinayagam *et al.*, 2013).

Conclusion

This article will not only enable researchers to get a comprehensive overview of tools available in the field of functional genomics but will also enable them to select the best tool(s) to carry out their task. Additionally, it will assist the development of new and better resources by highlighting the areas where no (or a few) resources exist.

Transcription Factor Databases

Edgar Wingender, geneXplain GmbH, Wolfenbüttel, Germany and University Medical Center Göttingen, Göttingen, Germany

Background

Transcription, i.e., the synthesis of an RNA strand that is complementary to a piece of genomic DNA of an organism, is an essential step of gene expression. To our present knowledge, it is the most tightly and subtly regulated mechanism of the whole process of making a gene product according to genomic instructions. Transcribing DNA into RNA is done by a small class of enzymes, the DNA-dependent RNA polymerases. To direct polymerase molecules to a specific place in the genome, the transcription start site (TSS), the assistance of additional factors is required, which are called transcription factors (TFs). In the beginning of the research on these factors, the focus was on a set of co-factors of the polymerase that we call today general transcription factors (GTFs). Best studied for bacteria are the sigma factors, for eukaryotic a set of GTFs is known such as TFIIA, TFIIB, TFIID-F, TFIIF. Some of these GTFs bind directly to the DNA with a more or less relaxed sequence-specificity, others are included through protein-protein interactions. They are involved in the assembly of the transcription complex at the core promoter, the region around the TATA-box at ~ -30 bp of the TSS and the TSS itself. A much larger set of DNA-binding TFs that bind to specific regulatory sequences, or cis-regulating elements, have been discovered later. In addition, there are factors involved in transcriptional regulation that do not bind directly to DNA by themselves, but are incorporated into DNA-bound complexes through protein-protein interactions. Depending on the TF definition applied, they may be included or some of them may be split off as separate class of, e.g., co-activators etc. In bacteria, we may have up to 300 TFs (Gama-Castro *et al.*, 2016), while the human genome may encode up to 2000 TFs (Wingender *et al.*, 2013), the exact number depending on the definition.

Aims of TF Databases

A TF database (TFDB) may first of all store information about TFs. In doing so, it should provide additional information rather than just serving as a specialized subsection of a comprehensive protein resource such as UniProt. Therefore, already the first compilation of TFs from 1988 that developed into the database TRANSFAC combined information about (eukaryotic) TFs with specifications of their DNA binding sites (Wingender, 1988). As an increasing amount of transcription factor binding sites (TFBSs) was gathered from the scientific literature, it was possible to complement the TFDB contents by binding sites models, for instance as consensus sequences, as positional weight matrices (PWMs) or as Hidden Markov Models (HMMs). Libraries of such models were compiled and are used now to computationally predict potential TFBSs in yet uncharacterized DNA sequences. Also on the side of the binding proteins, the increase of the number of known TFs and their characterization, in particular the mapping of their DNA-binding domains (DBDs), allowed to come up with corresponding domain models that became part of general protein motif collections like InterPro or of specialized TFDBs (see Fig. 1 for a simplified scheme). They are used to predict potential TFs in not yet annotated genomes, or to classify TFs according to their DBDs, e.g., in TFClass (Wingender *et al.*, 2013).

For the purpose of predicting corresponding entities (TFBSs or TFs), several of the TFDBs available today are accompanied with pieces of software that support these tasks.

Among the TFDBs that have been developed so far, some have a more comprehensive scope and try to cover the whole field of prokaryotic or eukaryotic TFs, while others are more focussed on certain taxa such as insects or plants. Some will be described in the following, others can be found in Table 1. Moreover, the individual TFDBs differ in the way their content has been curated, whether manually or by text mining approaches, or a mix of both. The exact method by which the contents have been gathered is not always clear.

TRANSFAC

The oldest still actively maintained database in the field is the TRANSFAC database. Its contents are basically structured in tables that provide information about the TFs (FACTOR table) or their genomic binding sites (SITE). All information in these tables has been manually extracted from the original publications. Semi-automatically retrieved are, however, data from high-throughput experiments such as ChIPseq data. Large numbers of genomic TF binding fragments can arise from these approaches, millions of them are stored in a separate table of the database (FRAGMENT).

On top of these entities, abstract models of DNA binding specificities as PWMs (MATRIX) or of DBDs (CLASS) have been implemented (Fig. 1), the contents of which are semi-manually curated. The entries of the MATRIX table are assigned to TFs of one of four taxonomic groups (vertebrates, insects, plants, and fungi). Many entries have been generated by TRANSFAC curators from information compiled in the SITE table. Other MATRIX entries were published in scientific reports and were included for documentary purposes. This dual purpose made it necessary to set up filters discriminating between those matrices that are suitable for predicting TFBSs and others, which were incorporated for archiving.

Fig. 1 Simplified scheme of content types of TFDBs. Individual databases usually focus on some of these content areas. As examples, the corresponding tables of the TRANSFAC database and associated resources have been indicated. “Factors” stands for information about transcription factors (TFs), “Sites” for TF binding sites (TFBS), either conventionally identified or obtained from high-throughput experiments such as ChIPseq, both pointing to each other. On top of these entities, abstract models of DNA-binding domains of TFs and of TFBSs are frequently provided for both descriptive and predictive purposes.

An accompanying resource is the database TRANSCompel, the concept of which has emerged from the COMPEL database on composite elements (CEs) (Kel *et al.*, 1995). These are binary or higher-order combinations of individual TFBSs, which together convey a qualitatively and/or quantitatively new regulatory feature to the associated gene. They serve as integrative modules, where two regulatory activities exert a synergistic effect; for instance, one TFBS of a CE may interact with a tissue-specific TF, while the partner site may convey the response to a certain signal transduction pathway. Another accompanying database is TRANSPro, a comprehensive compilation of the promoters of several genomes (human, mouse, rat, and the plant *Arabidopsis thaliana*). TRANSFAC is connected with TFClass, a classification system for TFs according to their DBDs, so far applied to mammalian TFs (Wingender *et al.*, 2018). Since 1999, another complementary information resource has been established that represents signaling pathways aiming at TFs (Heinemeyer *et al.*, 1999). This database, TRANSPATH, has been focussing on pathways that lead to the activation or inactivation of TFs, although its scope was expanded later on.

TRANSFAC strives to cover the whole area of eukaryotic TFs, although the coverage of different taxa may be significantly different.

First attempts to use TRANSFAC contents for the prediction of TFBSs made use of the information about the experimentally validated sites compiled in the SITE table. Soon after, partly based on TRANSFAC’s matrix library, several algorithms were developed that utilize PWMs for TF search, e.g., ConsInspector (Frech *et al.*, 1993), MATRIX SEARCH (Chen *et al.*, 1995), MatInspector (Quandt *et al.*, 1995), MATCH (Kel *et al.*, 2003a,b) and several others (see Relevant Websites Section). TRANSFAC itself is accompanied by MATCH (Kel *et al.*, 2003a,b). The program identifies TF binding sites at three different levels of stringency either minimizing the false positive or the false negative rate, or the rate of the sum of both error rates. The different algorithms mainly differ in the way how site scores are computed. In some of the earlier approaches some algorithms use matrix regularization (pseudo-counts) and forbidden nucleotides in order to account for specific constraints of the nucleotide distribution in the TF motifs. Similar to the MatInspector approach, MATCH applies specific weighting of PWM positions by information content of the nucleotide composition in the given position of the matrix. It was shown that this approach often increases precision of TF site recognition (Kondrakhin *et al.*, 2016). On top of MATCH results, the program F-Match identifies TF binding sites that are enriched in a set of regulatory sequences (e.g. a set of promoter sequences of co-regulated genes or a set of ChIP-seq peaks of active chromatin region). Combinations of predicted TF sites can be identified with a specific genetic algorithm implemented in the program CMA (Composite Module Analyst) (Kel *et al.*, 2006). CMA and other algorithms with similar scope were independently reviewed by Klepper *et al.* (2008).

The TRANSFAC database started in 1988 first as a private initiative and continued later as a public project. To secure long-term financial support, a company (BIOBASE) was established in 1999 to maintain and distribute the database commercially. An older version was kept in the public domain. Today, TRANSFAC is maintained, further developed and distributed by the company geneXplain. The FACTOR table of TRANSFAC has recently been made freely accessible.

Since its publication, the aims and ideas of the TRANSFAC database were adopted by a number of other databases, many of them also adding their own concepts.

JASPAR

JASPAR started as a carefully selected, non-redundant compilation of high-quality profiles, or position-specific scoring matrices that were derived from experimentally validated TF binding sites (Sandelin *et al.*, 2004). The database expanded over the years and more recently included third-generation binding models, which in contrast to PWMs or PSSMs consider position

Table 1 Overview of transcription factor databases, their scope and associated tools

Database name	URL	Species focus	Project start	Last updated	Brief summary	Tools	Country
3d-footprint	http://floresta.eead.csic.es/3dfootprint/	Eukaryotes		2017	Dedicated to structural data of DNA-binding proteins. Comprises clustering and classification of protein-DNA complexes.	Structure analysis, consensus literature miner, BLAST	Spain
AnimalTFDB2.0	http://bioinfo.life.hust.edu.cn/AnimalTFDB/	Vertebrates		2015?	General transcription factor (TF) database that focuses on curation and classification of genome-wide TFs, chromatin modifying proteins and transcription co-factors. The classification is based on DNA-binding domain characteristics.	TF prediction; BLAST	China
ArchaeaTF	http://bioinformatics.zj.cn/archaeatf/	Archaea	2006	2008	Database on (putative) transcription factors in Archaeal genomes. Due to annotated sequence characteristics, it can be useful for comparative genomics analysis of TFs in Archaea	Phylogenetic tree; BLAST	China
AthaMap	http://www.athamap.de/	Plants; Arabidopsis	2004	2016	Species-specific database on genome-wide putative transcription factor and small RNA binding sites in Arabidopsis thaliana. The sites are either experimentally verified or predicted by positional weight matrices representing TF binding specificities	TFBS and small/miRNA RNA target site search	Germany
ATRM (Arabidopsis Transcriptional Regulatory Map)	http://atrm.cbi.pku.edu.cn/	Plants; Arabidopsis	2014?	2017	Depicts the transcriptional regulatory network in Arabidopsis thaliana based on literature text mining and manual annotation		China
CIS-BP	http://cisbp.cabr.utoronto.ca/	Plants; Arabidopsis	2003?	2012?	Contains information on Arabidopsis thaliana transcription factors. The TF are classified as members of 50 families. The Catalog of Inferred Sequence Binding Preferences (CIS-BP). It documents a large number of TF binding motifs/matrices, also from a variety of other sources.	TF binding site prediction tools	US
CollectF	http://www.collectf.org/browse/home/	Eukaryotes	2014	2015	Database for TFBS in bacteria. All sites have been experimentally verified and manually curated.		Canada
CoryneRegNet	https://coryneregnet.compbio.sdu.dk/v6/index.html	Prokaryotes; Corynebacteria	2013?	2015	Reference database for TF in Corynebacteria and their regulatory networks. Comprises experimentally-verified as well as automatically predicted regulation data.	TFBS prediction tool	US
CTCFBSDB	http://insulatordb.uthsc.edu/	Eukaryotes		2012	Dedicated to CTCF binding sites and genome organization. Contains experimentally-verified as well as automatically predicted sites.	Site prediction tool	US
ctFbase	http://bioinformatics.zj.cn/ctFbase/Home.php	Cyanobacteria		2007	Database focused on putative transcription factors in the genomes of Cyanobacteria. Classification of TFs based on DBD characteristics.	BLAST; sequence alignment, phylogenetic tree	China
DBD	http://www.transcriptionfactor.org/index.cgi?Home	Eukaryotes	2008	2011	Genome-wide collection of putative TF with assignments to sequence specific DNA-binding domain families. The DBD database covers 930 sequenced genomes.		UK
DBTBS	http://dbtbs.hgc.jp/	Prokaryotes; Bacillus subtilis	1999	2008	Resource dedicated to experimentally validated TFBS in gene regulatory regions of Bacillus subtilis. All cis-elements (TFBS) in a promoter are depicted together with their positions.		Japan
iDMMPMM	http://autosome.ru/iDMMPMM/	Drosophila	2009	2009	Drosophila melanogaster collection of transcription factor DNA-binding motifs from several experimental sources	Genome Browser	Russia
DOOR ²	http://csbl.bmb.uga.edu/DOOR2/index.php#tabs-1	Prokaryotes	2009	2013	Comprehensive prokaryotic operon database with data from 2072 bacterial genomes. The operons are predicted based on essential genomic features. Contains transcription units from experiments and RNA-seq predictions.		US

ENCODE	https://www.encodeproject.org/	Human, mouse, worm, fly	2017	Collection of high-throughput data about functional DNA elements, including TF binding regions from ChIP-seq experiments conducted in different cell types.	US
Factorbook	http://www.factorbook.org/human/chipseq/tf/	Human, mouse	2012? 2017?	Factorbook summarizes the results of ENCODE TF ChIP-seq data, together with ChIP-seq of histone modification and nucleosome occupancy experiments	US
Fly Factor Survey	http://mccb.umassmed.edu/tfs/	Drosophila	2008? 2013?	Focuses on DNA-binding specificities of TF in Drosophila melanogaster based on results obtained from systematic application of the bacterial one-hybrid method.	USA
footprintDB	http://floresta.eead.csic.es/footprintdb/	Eukaryotes	2016 2017	Resource that collects TFs, TFBS and their DNA-binding specificity representing matrices from various sources.	Spain
Grassius	http://grassius.org/	Plants; Rice, Maize, Sorghum etc.	2008 2017	Collection of databases focused on gene regulation control in grass plants. Captures interactions of transcription factors with DNA-binding sites in promoter regions by literature curation and community contribution.	USA
GTRD	http://gtrd.biouml.org/	Human, mouse	2017	The Gene Transcription Regulation Database (GTRD) has a comprehensive collection of uniformly processed ChIP-seq data sets, allowing to deduce TFBS in human and mouse.	Russia
hmChIP	http://ijlab.biostat.jhsph.edu/database/cgi-bin/hmChIP.pl	Human, mouse	2011?	Resource to collect ChIP-chip and ChIP-seq data sets from experiments conducted in human and mouse cell lines or tissues.	USA
HOCOMOCO	http://hocomoco.autosome.ru/	Human, mouse	2017	The Homo sapiens Comprehensive Model Collection (HOCOMOCO) contains mono- and dinucleotide TF DNA-binding models for more than 1100 human and mouse factors.	Russia
HOMER	http://homer.ucsd.edu/homer/index.html	Eukaryotes	2010 2017	The HOMER website combines TF motif databases with a software for binding site prediction and next-generation sequencing analysis.	USA
HTPSELEX	http://ceg.vital-it.ch/htpselex/		2010	This database comprises sets of in vitro selected TFBS sequences obtained by SELEX and high-throughput SELEX experiments.	
HTRdb	http://www.lbbc.lbbc.unesp.br/htr/	Human	2009 2012?	Database on regulatory interactions between human transcription factors and their target genes. The interactions are experimentally verified and manually curated from the biomedical literature.	Switzerland
Islet Regulome Browser	http://gattaca.imppc.org/isletregulome/info			Visualization tool for maps of ChIP-seq derived TFBS in pancreatic islet and progenitor cells	
ITAK database	http://itak.feilab.net/cgi-bin/itak/db_home.cgi	Plants	2010 2016	Database for putative plant transcription factors and protein kinases predicted by the classifier software ITAK.	Brazil
JASPAR	http://jaspar.genereg.net/	Eukaryotes	2004 2017	Collection of non-redundant transcription factor DNA-binding models for multiple species. They are stored as Position Frequency Matrices (PFMs) and TF flexible models (TFFMs).	UK
MtbRegList	http://mtbreglist.genap.ca/MtbRegList/www/index.php	Prokaryotes; M. tuberculosis	2005 2005	Resource focused on the analysis of gene regulation mechanisms in Mycobacterium tuberculosis. Contains transcription start sites and TFBS as well as the respective transcription factors.	Canada
newPLACE	https://sogo.dna.affrc.go.jp/cgi-bin/sogo.cgi?lang=en&pj=640&action=page&page=newplace	Plants	1999 2007?	Database of motifs detected in plant cis-acting regulatory DNA elements, extracted from published literature.	Japan
NURSA	https://www.nursa.org/nursa/index.jsf	Human, mouse, rat	2003 2017	A website dedicated to accrue information on nuclear receptors and co-regulators and their physiological roles. The data includes NR ligands and transcriptional targets.	USA
P2TF	http://www.p2tf.org/	Prokaryotes	2012?	BLAST, Genome Browser	France (Continued)

Table 1 Continued

Database name	URL	Species focus	Project start	Last updated	Brief summary	Tools	Country
PAZAR	http://www.pazar.info/	Eukaryotes		will retire end of 2018	The Predicted Prokaryotic Transcription Factors (P2TF) database includes putative TFs of a large number of bacterial and archaeal genomes as well as a TF classification.		Canada
Plant Cistrome Database	http://neomorph.salk.edu/dap_web/pages/index.php	Plants; Arabidopsis; Maize		2016	Website hosting TF and regulatory sequence collections. It provides a software framework for regulatory sequence annotation tasks.	Genome Browser, Matrix comparison and clustering	USA
PlantPAN 2.0	http://plantpan2.https.ncu.edu.tw/index.html	Plants	2008	2015	Resource that provides TF binding profiles generated out of DAP-seq experiments in plants.	Network visualization, promoter analysis	Taiwan
PlantRegulome	http://plantregulome.org/	Plants; Arabidopsis	2013	2013	The Plant Promoter Analysis Navigator (PlantPAN) contains TFs, binding sites, and motifs for 76 plant species and allows to analyze promoters and to construct regulatory networks.	Regulatory network visualization	USA
PlantTFDB	http://planttfdb.cbi.pku.edu.cn/	Plants	2010	2017	Focuses on creating maps of gene regulatory information in various developmental stages, tissues and cell types of Arabidopsis thaliana.	TF prediction server; tools for regulation prediction and functional enrichment analyses	China
PlnTFDB	http://plntfdb.bio.uni-potsdam.de/v3.0/	Plants	2009		Database storing TF from 165 plant species as a result from an automated prediction pipeline. The TF are classified by DBD family assignments.	BLAST	Germany
PRODORIC	http://www.prodoric.de/	Prokaryotes	2001	2008	The resource aims to identify and classify all plant genes involved in transcriptional control. The TF family classification is based on characteristic domains described in the literature.	Genome Browser, network analysis and visualization	Germany
RegulonDB	http://regulondb.ccg.unam.mx/	Prokaryotes; E. coli	1998	2017	A database containing comprehensive gene regulation and expression information in prokaryotes. It includes experimentally validated and manually curated transcription factor binding sites. It's accompanied by bioinformatics tools for the prediction, analysis and visualization of gene regulatory networks.	Regulatory network visualization, genome browser, text mining, PWM clustering, classification browser	Mexico
ReMap 2018	http://tagc.univ-mrs.fr/remap/index.php	Human	2015	2017	Database dedicated to comprehensively model the transcriptional regulatory network in E. Coli K-12. It includes information on transcription units, operons and regulons. The data is manually curated from peer-reviewed literature.	Statistical search of TF binding peaks	France
Riken TFdb	http://genome.gsc.riken.jp/TFdb/	Mouse		2004?	A platform that collects TFBS ChIP-seq data sets from ENCODE, GEO and ArrayExpress. Peaks have been uniformly processed and are available for either in total or as non-redundant merged peaks.		Japan
ScerTF	http://stormo.wustl.edu/ScerTF	Yeast		2012?	A database containing a set of mouse non-redundant transcription factors and their related genes.	TFBS prediction	USA
STIFDB	http://caps.ncbs.res.in/stifdb2/	Plants; Arabidopsis, rice		2012	A resource that collects non-redundant position weight matrices (PWMs) for yeast transcription factors from literature and public database sources.	Blast	India
TcoF	http://www.cbric.kau.ac.sa/tcof/	Human	2010	2017	The Stress Responsive Transcription Factor Database (STIFDB) is a comprehensive set of biotic and abiotic stress responsive genes and their potential TFBS in respective promoter regions in Arabidopsis thaliana and Oryza sativa.		Saudi-Arabia
TEC	https://shigen.nig.ac.jp/ecoli/tec/top/	Prokaryotes; E. coli	2010?	2016?	A database focusing on human transcription co-factors and TF interacting proteins.		Japan

TFBSshape	http://rohsiab.cmb.usc.edu/TFBSshape/	Eukaryotes	2014?	TEC contains regulatory targets for TFs and sigma factors in <i>E. coli</i> K-12 determined by SELEX-chip screening. TFBSshape includes predicted DNA shape features for TFBS, characterizing DNA binding specificities of TFs from 23 species.	USA
TFcat	http://www.tfcat.ca/	Human, mouse	2009?	Catalog of mouse and human transcription factors (TF) based manual curation from the biomedical literature. In addition, TF encoding genes have been predicted based on sequence analysis. DNA-binding TF are assigned to a structural classification system.	Canada
TFcheckpoint	http://www.tfcheckpoint.org/	Human, mouse, rat	2014?	Manually curated database for human, mouse and rat TFs based on public database and literature sources.	Norway
Tfe	http://cisreg.cmmr.ubc.ca/cgi-bin/tfe/home.pl	Human, mouse, rat	2012	The Transcription factor encyclopedia (Tfe) aims to create encyclopedic articles for each well-studied TF.	Canada
TFindit	http://bioinfopen.uncc.edu/tfindit/	Eukaryotes	2012	Database and web service for structural information of transcription factor (TF)-DNA interactions. It contains pairs of bound and unbound transcription factor structures and homologous TF-DNA complex structures.	USA
TRANSFAC	http://genexplain.com/transfac/ Public: http://gene-regulation.com/pub/databases.html Factor search: http://factor.genexplain.com/cgi-bin/transfac_factor/search.cgi http://www.mgs.bionet.nsc.ru/mgs/gmw/trrd/	Eukaryotes	1988	TRANSFAC® is the database of eukaryotic transcription factors, their genomic binding sites and DNA-binding profiles. Its TFBS data is experimentally verified and manually curated from peer-reviewed literature.	Germany
TRRD	http://www.mgs.bionet.nsc.ru/mgs/gmw/trrd/	Eukaryotes	1995	The Transcription Regulatory Regions Database (TRRD) collects information on structural and functional organization of transcriptional regulatory regions of eukaryotic genes. All data in TRRD has been experimentally verified.	Russia
TRRUST	http://www.grnpedia.org/trust/	Human, mouse	2014	Manually curated database of human and mouse transcriptional regulatory networks. For a large part of the stored TF-target gene relations, the mode of regulation (activation or repression) is provided.	South Korea
UniProbe	http://the_brain.bwh.harvard.edu/uniprobe/	Eukaryotes	2008	The UniPROBE (Universal PBM Resource for Oligonucleotide Binding Evaluation) database contains data on in vitro DNA-binding specificities of proteins created by the universal protein binding microarray (PBM) experimental method.	USA
Yeastract	http://www.yeasttract.com/index.php	Yeast	2006	YEASTRACT (Yeast Search for Transcriptional Regulators And Consensus Tracking) is a curated database of regulatory interactions between TF and target genes in <i>Saccharomyces cerevisiae</i> .	Portugal
YefasCo	http://yefasco.ccbr.utoronto.ca/	Yeast	2012	The site provides a collection of TF specificities for <i>Saccharomyces cerevisiae</i> as position frequency matrices (PFM) or position weight matrices (PWM).	Canada

interdependencies within and variable lengths of the TF binding motifs. These Transcription Factor Flexible Models (TFFMs) are built with the help of hidden Markov models (HMMs) (Mathelier and Wasserman, 2013). The TFFMs of the provided library have been created from ChIP-seq data coming from the ENCODE project. Software tools for the application of these advanced binding models accompany the library. They are complemented by tools that support the creation of new TFFMs as well as to scan sequences with them (Mathelier et al., 2016). – As for the factor side, JASPAR is complemented by TFE, a transcription factor encyclopedia, which so far as compiled more than 800 expert-written articles about individual TFs.

Plant TFs

Two actively maintained resources for plant TFs have to be highlighted. One is **PlantTFDB** from Peking University, which covers properties of TFs from so far 165 plant species. Using an automated TF prediction pipeline, more than 320,000 TFs were identified to be encoded in plant genomes and can be browsed by (DBD) family assignments. Making use of a related resource of the same group, PlantRegMap, binding site and binding motif information has been made available as well (Jin et al., 2017). TFBSs have been partly taken from literature, where experimental evidence was given, or predicted by using the binding motif information. – Another program to identify TFs encoded in plant genomes is iTAK. It was trained with contents of PlantTFDB and others, and the results are provided online as database (Zheng et al., 2016). In addition, there are several databases that focus on individual species, mostly the best-studied plant organism *Arabidopsis thaliana*, such as AthaMap (see also Table 1) (Hehl et al., 2016).

Other Model Organisms

There are several other TFDBs that provide corresponding information with different emphasis on individual binding sites, high-throughput data on binding regions, or binding motifs for the factors of, e.g., *Drosophila* (Fly Factor Survey; Zhu et al., 2011) or yeast (Yeasttract; Teixeira et al., 2014).

TFDBs on Prokaryotic Transcription Factors

One of the most popular databases about entities of prokaryotic transcription is **RegulonDB** (Huerta et al., 1998). Structurally similar to TRANSFAC, the early database version provided in-depth information about *E. coli* TFs and their binding sites. As a unique feature, RegulonDB put the co-regulation of genes or operons in the focus. By time, the database broadened its scope even further by integrating information about regulatory interactions at genes encoding components of defined metabolic pathways with the signals triggering them into so-called Genetic Sensory-Response units (SENSOR units). – A similar resource focussing on *Bacillus subtilis*, **DBTBS**, has been released in 2000 by a team from Tokyo University (Ishii et al., 2001).

With regard to the range of organisms covered, the database **PRODORIC** had a broader approach since it aimed at the whole plethora of prokaryotic organisms. Otherwise, it has similar aims as RegulonDB and a structure resembling TRANSFAC (Münch et al., 2003). Later, the database was complemented with a rich set of software tools (Grote et al., 2009). Among them are a site scanning software, Virtual Footprint, supporting sensitive searches for single or composite TF sites in bacterial genomes. It also visualizes search results in the context of the whole bacterial genome.

Additional Collections of Binding Sites and Motifs

ENCODE (Encyclopedia of DNA Elements) is a consortial project that collects high-throughput data about functional DNA elements, among them TF binding regions from, e.g., ChIPseq studies (Davis et al., 2017). Its main focus is on the human genome, but several model organisms are covered as well. Binding motifs have been extracted from ENCODE datasets that refer to defined TFs, usually with the MEME-ChIP software suite (Machanick and Bailey, 2011), and have been compiled in Factorbook (Wang et al., 2012). At present, it shows binding motifs of 167 TFs derived from 837 experiments.

A principally similar approach, but using pre-processed high-throughput data provided by GTRD (Gene Transcription Regulation Database; Yevshin et al., 2017) and a novel motif discovery tool (ChIPMunk; Kulakovskiy et al., 2010), led to the generation of HOCOMOCO, a collection of mono- and dinucleotide matrices for human and mouse TFs (Kulakovskiy et al., 2018).

Based on a novel experimental approach, the UniPROBE (Universal PBM Resource for Oligonucleotide Binding Evaluation) database has been generated (Hume et al., 2015). The underlying data were obtained by using protein binding microarrays (PBMs) of synthetic oligonucleotides (decamers) to determine those sequences that are suitable to interact with a test protein or its DNA-binding domain in vitro (Mukherjee et al., 2004).

Introduction

The central dogma of molecular biology involves transcription and translation of genes leading to formation of proteins to carry out specific biological functions. Activation and suppression of this so-called “gene expression” by DNA binding proteins is a fundamental regulatory mechanism involving chromatin modification and transcription complexes to initiate RNA synthesis (Announcement, 1996). In human and other higher organisms, transcription involves binding of a specific group of proteins (known as transcription factors) to and unzipping of local regions in the double helical genomic DNA into two separate strands and synthesis of messenger RNA (mRNA) from one of them. Apart from transcription, DNA recognition by proteins is crucial in host response to certain pathogens (some pathogen DNAs can be recognized by “DNA sensors”), transfer of genetic information, cell differentiation, packaging, rearrangement, replication and repair (Wold, 1997; Dalrymple *et al.*, 2001; Wang *et al.*, 2000; Lieb *et al.*, 2001; Ofra *et al.*, 2007; Luscombe *et al.*, 2000; Walter *et al.*, 2009; Hashimoto *et al.*, 2003; Ptashne, 2005; Dillon and Dorman, 2010; Thanbichler *et al.*, 2005; Kow *et al.*, 2007; Kamashev, 2000). All such interactions proceed by the binding of proteins to (usually specific) DNA sequences and the formation of a protein-DNA complex (Luscombe *et al.*, 2000). The understanding of DNA-protein interactions is therefore extremely important to understand the fundamental processes of life.

The interaction between DNA-binding proteins and their target DNA is often accompanied by large conformational changes in either or both of them (Thompson and Landy, 1988; Paull *et al.*, 1993; Masse *et al.*, 2002; Andrabi *et al.*, 2014). These conformational changes facilitate and stabilize the formation of a protein-DNA complex, enabling the desired molecular events to take place. Different types of conformational changes have been confirmed by experimental data, e.g., an increase in superhelical density of DNA and bending and twisting of DNA are well documented (Beloin *et al.*, 2003; Tapias *et al.*, 2000; Noy *et al.*, 2016).

This review focuses on the understanding of the mechanism of protein-DNA interactions and their role in various biological processes, gives a broad overview of the nature of conformational changes in both protein and DNA in the formation of protein-DNA complex and the factors affecting its stability. We also aim to review the experimental and computational techniques to understand the structural and conformational changes in protein and DNA to form a stable complex. This review also investigates the current understanding of the role of DNA structure and dynamics in protein DNA interactions and highlights various unanswered questions on the subject.

Representative Systems of Protein-DNA Interactions

As stated above, the interactions between protein and DNA play a central role in a variety of biological processes such as transcription factors binding to DNA, DNA modifications, viral infection and chromosomal packing. Some of these interactions, such as transcription factor binding occur while the interacting sequence is still a part of a genomic DNA, which is millions of times larger, whereas other interactions may potentially be with a free and small DNA fragment in the cytoplasm (Beloin *et al.*, 2003). A protein on the other hand mostly acts as a complete unit, as a monomer or a complex formed by oligomerization on its own copies, with other co-factors or as a small number of subunits (e.g., histones) (Rouvière-Yaniv *et al.*, 1979; Luger *et al.*, 1997; Dillon and Dorman, 2010; Thanbichler *et al.*, 2005; Lia *et al.*, 2003). DNA-recognition in a genome towards gene expression requires rapid binding of modifying enzymes, polymerases, repressors and activators to their site of action on a large, packaged DNA, not always easily “visible” to the acting proteins (Gasser and Laemmli, 1987). The interaction between a protein and its “target” DNA in transcription factor binding promotes or suppresses specific genes and the corresponding proteins are called *activators* and *repressors* respectively. One of the most widely studied systems is the repressor protein responsible for switching on and off the *lac* and *lambda* phage genes of *Escherichia coli* (Matthews *et al.*, 1982; Kamashev *et al.*, 1995). The inactivation of *lac* and *lambda* repressor proteins leads to the expression of *lac* and *lambda* gene respectively. The process of binding of transcription factor is crucial, in general, for any such processes. The inappropriate binding of transcription factors results in alterations in gene expression, which has been found to be a cause of disorders (Jimenez-Sanchez *et al.*, 2001) and medical conditions in humans (Lee and Young, 2013; Farnham, 2009).

Another widely studied model system of protein-DNA interactions is related to the packing of chromosomes (Dillon and Dorman, 2010; Thanbichler *et al.*, 2005). The chromosomes consist of incredibly long DNA chains, which fold and compactify to protein-DNA complexes called chromatids (Fischle *et al.*, 2003). The DNA binding proteins involved in this process can be classified into histones and nonhistones chromosomal proteins. Histone proteins form nucleosomes which are attached by DNA string, forming a *bead-string* kind of structure at their first level of organization.

Role of protein-DNA recognition in host defense against invading pathogens is also of great significance so much so that in some cases pathogen DNA itself can act as a vaccine (Rice *et al.*, 1999; Modlin, 2000). Examples of protein-DNA interactions in host defense are CpG-rich viral DNA like simplex virus (HSV-1), HSV-2, and murine cytomegalovirus (MCMV), which are recognized by TLR9 resulting in activation of inflammatory cytokinesis and type 1 IFN secretion (Hochrein *et al.*, 2004; Krug *et al.*, 2004a,b; Lund *et al.*, 2003; Tabeta *et al.*, 2004; Akira *et al.*, 2006; Herzner *et al.*, 2015; Manders and Thomas, 2000; Dell’Oste *et al.*, 2015).

It may be noted that, although more common and widely investigated, it is not always the protein, which acts on DNA and hunts for its targets. As an example of the opposite, DNA fragments, binding to protein are known to stabilize proteins protecting them against misfolding and aggregation and thus leading to formation of a stable structure (Jolly and Morimoto, 2000; Morimoto, 1998; Wu, 1995).

DNA-Binding Protein Structures, Dynamics and Conformational Changes

Experimental techniques like X-ray crystallography and NMR have been employed to give high resolution structures of DNA-protein complexes in crystalline state and in solution respectively (Spolar and Record, 1994; Garvie and Wolberger, 2001). Many studies have shown large conformational changes in the structures of both the DNA and proteins during sequence-specific binding (Kalodimos, 2004; Kalodimos *et al.*, 2002; Spolar and Record, 1994). The conformational changes in DNA vary from smooth change in bending deformations to drastic changes resulting in disruption of base pair stacking, base flipping, sharp bends and kinks in the helical axis (Schultz *et al.*, 1991; McClarin *et al.*, 1986; Kim *et al.*, 1990; Honnappa *et al.*, 2005). Two key questions that have been investigated in details are:

"How a protein's binding nonspecifically to DNA, preceding the specific interaction, brings out a change in the structural and dynamic properties of DNA?" and "How does a complex undergo transitions from nonspecific to specific interactions".

To address these questions, Kalodimos (2004) studied *lac* repressor and categorized its DNA-binding domain on the basis of structure and dynamics in the free state and non-specifically bound state to DNA. In the study, the authors have reported the high-resolution structures of the dimeric *lac* repressor DNA-binding domain bound to an 18-base pair non-specific DNA fragment by imposing 2412 experimental restraints on multidimensional NMR spectroscopy. The authors did a comparison of the nonspecific and specific binding modes to determine the changes that occurred due to specific binding. The calculations for protein-DNA docking were performed (Brünger *et al.*, 1998) using HADDOCK setup and protocols, which are a handy set of tools for studying protein-DNA interactions *de novo* (Brünger *et al.*, 1998; Dominguez *et al.*, 2003). The protein in a non-specific complex is rotated by an additional ~ 25 degrees relative to DNA, when compared with the specific complex. Some of the residues (Tyr7, Gln18, and Arg22 in this complex), which play a key role in specific interaction, are found to undergo shifting and twisting to participate in hydrogen bonding and electrostatic interactions in the case of their corresponding non-specific complex. The interface of protein-DNA in case of non-specific complex in this system is found to be highly flexible in contrast to the rigid interface in the case of specific complex, thus implicating a role of conformational dynamics in specificity. In this system and in general, the atomic arrangements of protein-DNA complex are significantly altered in their nonspecific to specific transitions of interactions, which may be crucial in target search followed by complex formation with the genomic target DNA. In a recent study by Corona and Guo (2016), authors performed a comparative analysis of this protein-DNA complex to investigate the structural features that contributes to the binding specificity. Based on the binding specificity DNA-protein complex has been categorized as (1) Highly specific (HS) (2) multi-specific (MS) and (3) nonspecific (NS). From the analysis of conformational changes between bound and unbound states, authors found HS and MS to have larger conformational changes and flexibility in both bound and unbound states.

In another study by Velmurugu *et al.* (2016), dynamic conformational changes were studied for a DNA-repair protein radiation-sensitive 4 (Rad4; yeast XPC ortholog) recognition of the damaged site on DNA by using temperature-jump spectroscopy. One of the key finding of the study was the role of DNA deformability which is found to be the key factor that helps in a rapid search of the damaged site by DNA-repair protein. Specifically, the RAD4 recognizes the damaged site through twist-open mechanism in which twisting assists in inter-converting RAD4 from search mode to interrogation mode. The role of β -hairpin here is essential for the nucleotide flipping. The conformational changes compatible with rapid diffusion on DNA makes RAD4 stall preferentially at these sites offering time for DNA to open.

Insights into the conformational dynamics of protein-DNA interactions, not accessible to crystal structures determined by X-ray can be gleaned by NMR relaxation of backbone amides (Akke, 2002). Such studies have resulted in the understanding that most of the functional processes, such as docking, protein folding, allosteric transitions are associated with slow motion of *motor* domains (on the time scale of μ s to ms). Most of the residues that perform the motion at this time scale are found to be involved in both specific and nonspecific binding. Motion on this time scale and the flexibility of the complex facilitates the conformational transitions and the search of specific sites respectively.

To understand the effect of conformational dynamics in protein-DNA recognition Chu *et al.*, (2014) developed a two-basin structure based model to understand the dynamics of *Sulfolobus solfataricus* DNA Y-family polymerase IV (DPO4) when it binds to DNA. A two-basin structure based model (SBM) was developed with electrostatic interaction given by Debye-Huckel model. Thermodynamic and kinetic simulations were performed to investigate the conformational transitions of DPO4 during the process of binding to the target site on DNA. In the study, authors have found that DPO4 maintains multiple conformational equilibrium stages during the process of binding and the distribution of conformations vary at different stages of binding. By varying the strength of electrostatic interactions and the flexibility of the linkers, the authors showed the way DPO4 dynamically regulates the DNA recognition.

In yet another recent study using NMR spectroscopy, Desjardins *et al.* (2016) investigated the mechanism of binding of the Ets-1 transcription factor to DNA. Ets-1 belonging to ETS family of eukaryotic transcription factors is auto-inhibited by serine-rich region (SRR) and helical inhibitory module (IM). The structural and dynamic features of the Ets-1 were characterized for both specific and nonspecific binding of ETS-1 to 12 bp of oligonucleotides. On binding to both nonspecific and specific DNA, the N-terminal sequences are found to be predominantly unfolded, but still, sample ordered conformations. With specific DNA, the backbone undergoes more structural and dynamic changes and arginine/lysine side chains of the core ETS domains are much larger in comparison to non-specific binding. The study supports the general model that the Ets-1 form non-specific binding *via* electrostatic interactions and hydrogen bonding assist in the formation of well-ordered specific complexes with DNA.

Conformational changes in protein-DNA complexes are not always associated with target search as the physical cellular environments such as varying pH, temperature as well as site-specific chemical modification (phosphorylation and methylation) often lead to the formation and alteration of the oligomeric states of protein-DNA complexes (Andrabi *et al.*, 2014). Irrespective of the mechanisms involved in the conformational changes, two or more conformations of proteins in DNA-bound and unbound states may be compared to investigate the differences caused by complex formation. Based on this approach, we recently surveyed and analyzed the conformational changes in a large number of protein-DNA complex (Andrabi *et al.*, 2014). We addressed three issues of conformational changes in DNA-binding proteins: (a) types of conformational changes and their distribution among different proteins with respect to charge and dipole moments, (b) Intrinsic flexibility of unbound DNA and its role in conformational change (c) contributions of conformational change to the stability and specificity of DNA-protein complex. Six groups of conformational changes were identified and related to their biological implications. Proteins in one of these groups undergoing little conformational change “the rigid group” were found to form smaller number of contacts with DNA in comparison to proteins, which undergo large conformational change. We also reported that the degree of conformational change in protein-DNA complex increases the stability and specificity of the complex. Normal mode analysis was used to analyze the extent and direction of conformational changes in protein in some classes of DNA-binding proteins. The amount of conformational changes occurring in a protein was found to depend on the polarity of proteins. The proteins with positive charge interact mostly with the negatively charged backbone of DNA and thereby undergo least conformational change. However, for hydrophobic residues like Cys, Ala and Gly, proteins undergo large conformational changes at the interface to adjust for the binding.

Role of DNA Structure and Dynamics

Binding of proteins to its specific site of action on DNA is usually accompanied by diffusion and nonspecific binding to DNA (Berg and von Hippel, 1985). It has been proposed that the proteins undergoing three-dimensional diffusive motion in cytoplasm bind nonspecifically to DNA and then undergo one-dimensional sliding motion to reach its specific binding site on DNA (Shimamoto, 1999; Halford and Marko, 2004; Kalodimos, 2004; Esadze *et al.*, 2014). This mechanism is termed as facilitated diffusion mechanism (Berg *et al.*, 1981; Richter and Eigen, 1974) and has been proposed to justify the fast rate of binding of protein to genomic DNA (see Fig. 1 for the general process of TFs finding their targets in genomic DNA). This non-specific binding of protein and DNA is a result of electrostatic interactions between the negatively charged phosphate backbone and protein.

The specific binding of proteins to DNA involves two types of mechanisms: one is the hydrogen bond formation with specific sequence along the major groove and the other is sequence dependent deformation of DNA (Fuxreiter *et al.*, 2011; Rohs *et al.*, 2009b; Ahmad *et al.*, 2006). They are respectively termed as *sequence* and *shape* readout (earlier known as *direct* and *indirect* readout). In some protein-DNA complexes, the bending of DNA ends up with huge conformational changes in the structure of

Fig. 1 Diffusion mechanisms of transcription factors trying to find their targets in genomic DNA (for simplicity genomic DNA is shown as a straight helix instead of chromatin folding): The TFs are reported to undergo electrostatically dominated non-specific interactions with DNA, which undergoes a non-specific to specific hydrogen-bond dominated interaction transition upon reaching the targets. Diffusions processes themselves during non-specific association between protein and DNA occurs through multiple events such as hopping, jumping, inter-segmental transfer and three-dimensional diffusion.

DNA and is found to deviate from B-form of double helix. The role of dynamics is not just limited to non-specific interactions but it also plays an important role in specific interactions between protein and DNA. As an example, Sox2 proteins cause a large DNA bend when they bind to their genomic targets requiring substantial interaction energy, which is often provided by partner protein-protein interactions with cofactors (Hou *et al.*, 2017; Kamachi *et al.*, 1999; Scaffidi and Bianchi, 2001). The flexible and positively charged tails of proteins assist in fine-tuning the specificity in case of transcription factors (Fuxreiter *et al.*, 2011; Rohs *et al.*, 2010).

Molecular dynamics (MD) is the principal technique to investigate the detailed molecular mechanism of protein-DNA interactions, partly because actual experimental procedures to observe the process of protein-DNA interactions are beyond the technological capabilities of researchers. There have been a number of successful efforts in applying MD to understand and interpret observed biological knowledge of protein-DNA interactions in the cellular contexts. For example, in a recent MD study of telomere repeat binding factors (TRF1 and TRF2), the dynamics of individual amino acids chains suggested that they could contribute to the recognition of more than one base pair (Etheve *et al.*, 2016; Garton and Laughton, 2013; Jolma *et al.*, 2010). The study helped to resolve conflicting experimental data (Luscombe *et al.*, 2000; Garton and Laughton, 2013). In a study by Tan *et al.* (2016) authors emphasized the dynamic aspects of nonspecific protein-DNA interactions. The dynamic coupling between protein binding to DNA and the change in the structure of DNA was investigated. Protein binding to DNA changes the DNA structure, which in turn modifies the mechanics of proteins along the DNA scaffold and thereby its interaction dynamics (Bhattacharjee and Levy, 2014a,b; Rohs *et al.*, 2009a,b; Stella *et al.*, 2010). Molecular dynamics simulations have been performed on Coarse-grained model of DNA-binding proteins to understand the dynamic couplings among protein-DNA binding, sliding of protein along DNA and bending of DNA. Simulations have been performed on bacterial architectural protein HU (Rouvière-Yaniv *et al.*, 1979) and 14 other DNA-binding proteins. At long time-scales, it has been found that the sliding motion of HU is associated with DNA bending different from *induced-fit* and *population-shift*. At shorter time scales, the HU is found to pause when the DNA is highly bent and starts to move when DNA returns to less bent structure. Thus the sliding motion is found to largely depend on the DNA bending dynamics.

Issues in Protein-DNA Interactions Predictions

The interplay between protein and DNA are ubiquitous in nature and governs several cellular processes (replication, transcription, translation, chromosomal packing, *etc.*) crucial for growth and survival of any living organism. Given its importance, the field of protein DNA interaction has been studied by many researchers with a focus on the development of tools and techniques for identification of DNA binding site in proteins, DNA binding proteins from sequence or structure and transcription factor binding site on genomic DNA. In the following sections, we review the progress made on these issues.

Prediction of DNA Binding Residues and DNA Binding Proteins

The binding of DNA to the protein is very specific where DNA binds to a particular region of the protein usually termed as the binding site, defined by the group of residues that are essential for the biological function and whose mutations can result in attenuation/loss of function. An accurate estimation of DNA-binding site and DNA-binding proteins thus is of utmost significance and can provide an insight into the various functions of the protein and also in designing novel therapeutics. Many experimental and computational methods have been developed for prediction of DNA binding site and DNA-binding proteins. Experimental methods for direct assessment of DNA-binding specificities include chromatin immunoprecipitation (ChIP) (Bardet *et al.*, 2013; Johnson *et al.*, 2007), MicroChIP (Luscombe *et al.*, 2001), Fast ChIP (Mandel-Gutfreund and Margalit, 1998), electrophoretic mobility shift assays (EMSAs) (Jones *et al.*, 1999, 2003), peptide nucleic acid (PNA)-assisted identification of RNA binding proteins (RBPs) (PAIR) (Olson *et al.*, 1998), X-ray crystallography (Orengo *et al.*, 1997) and nuclear magnetic resonance (NMR) spectroscopy (Ponting *et al.*, 1999). With the growing advancement in associated computational technologies and machine learning methods, several bioinformatics methods have also been developed for the prediction of DNA binding site complementing experimental procedures. The computational approaches for prediction of DNA binding site and DNA-binding proteins can be broadly classified into three categories: sequenced based approaches, structure-based approaches and homology modeling and threading (discussed in Section “Computational Methods for Investigating Protein-DNA Interactions”) (Si *et al.*, 2015).

Many sequence- and structure-based methods for prediction of DNA-binding site and DNA-binding proteins rely on the identification of homologous sequences/structures with known DNA-binding site information. In sequence-based methods, based on sequence alignment of the homologous sequence and query protein, DNA binding site is inferred from the homologous sequence. Structure-based methods are typically utilized when the crystal structure of the protein of interest is known. In this approach, the probable DNA binding site is inferred by comparing the binding site of the known DNA binding proteins and the query protein (Fig. 2). Homology based methods are effective when similar proteins with known binding sites are available, which is often not the case for many DNA-binding proteins. Several studies have utilized non-comparative sequence and structure-based methods for identification of DNA-binding site and DNA binding proteins. These methods try to develop an association between the *descriptors* or *features* of subsequences or substructures in a protein and implicitly model their propensity individually or cumulatively to binding DNA (Ahmad and Sarai, 2005; Yan *et al.*, 2006; Hwang *et al.*, 2007; Ofra *et al.*, 2007; Wu *et al.*, 2009; Carson *et al.*, 2010; Alibés *et al.*, 2010b; Xiong *et al.*, 2011; Li *et al.*, 2013, 2014a,b; Zhao *et al.*, 2014; Peled *et al.*, 2016). Various sequence-based features include amino acid sequence/residue type, sequence conservation, global composition of amino acids.

Fig. 2 Sequence and structure based predictions of protein-DNA interactions. Two groups of widely investigated problems are (a) identification of DNA-binding residues for known DBPs and (b) identifying novel candidate DBPs from a list of proteins.

Structure-based features include structural motifs, structural neighborhood, structural flexibility, secondary structure, accessible surface area (ASA), hydrophobicity, electrostatic potentials, net charge, and dipole and quadrupole moments (Si *et al.*, 2015, Ahmad and Sarai, 2004). Once the features have been identified, the next step is to develop a computational model that can find a quantitative predictability of DNA binding from these features. Among the earliest efforts, Ahmad *et al.* (2004) examined the protein DNA binding residues in terms of local amino acid composition, solvent accessible surface area, and secondary structure. Employing this knowledge a neural network model was developed to identify the DNA binding site and DNA binding proteins directly from sequence. Later on, the position-specific scoring matrix (PSSM) profiles were also incorporated into the model to improve the accuracy of the DNA-binding site prediction (Ahmad and Sarai, 2005). Utilizing the same dataset as by Ahmad *et al.*, Kuznetsov *et al.* (2006) used sequence and structure features to identify DNA binding site employing Support Vector Machine, a supervised pattern recognition method. Yan *et al.* (2006) utilized the Naive Bayes classifier and sequence based features (identity of central and neighboring amino acid residues) to predict the DNA binding residues in DNA binding proteins. Using amino acid residue properties *i.e.* molecular mass, hydrophobicity index and side chain *pka* values, Wang and Brown (2006) developed SVM classifier for identification of DNA binding site from primary sequence data. Hwang *et al.* (2007) employed machine learning techniques (kernel logistic regression, support vector machine and penalized logistic regression) for prediction of DNA binding sites from primary sequences with/without the use of PSSM profiles. Employing features derived from sequence and structure, Bhardwaj and Lu (2007) used the SVM classifier to predict DNA binding residues. Chu *et al.* (2009) used protein secondary structures for identification of DNA binding sites in transcription factors. More recently, Zhou *et al.* (2017) have utilized a novel residue encoding method termed as Position Specific Score Matrix (PSSM) Relation Transformation (PSSM-RT), to encode amino acid residues using the evolutionary information between residues and an ensemble learning classifier (EL_PSSM-RT) for prediction of DNA binding site. In a study by Yan and Kurgan (2017), authors have developed a novel method that accurately predicts DNA- and RNA-binding residues as well as DNA- and RNA-binding proteins using sequence-derived features (physicochemical and biochemical properties) and logistic regression model.

Several machine-learning approaches have also been developed for the related problem of identifying the DNA binding sites in proteins using evolutionary information. Similar to prediction of DNA binding residues, both sequence based (Cai and Lin, 2003; Yu *et al.*, 2006; Kumar *et al.*, 2007, 2009; Langlois and Lu, 2010; Huang *et al.*, 2011; Lin *et al.*, 2011) and structure-based methods (Stawiski *et al.*, 2003; Ahmad and Sarai, 2004; Bhardwaj and Lu, 2007; Szilágyi and Skolnick, 2006; Nimrod *et al.*, 2009, 2010; Zhou and Yan, 2011; Zhao *et al.*, 2014) have been developed for the identification of DNA binding proteins. Cai and Lin (2003) utilized pseudo amino acid composition and a group of nonlinear features derived from primary protein sequence to develop SVM for prediction of DNA binding proteins. Yu *et al.* (2006) utilizing sequence derived physicochemical properties and SVM proposed the binary classifications for rRNA-, RNA-, and DNA-binding proteins. Shao *et al.* (2009) developed a classifier based on SVM to differentiate between DNA/RNA binding proteins from non-nucleic acid binding proteins. Kumar *et al.* (2009) proposed a method, DNA-Prot, to determine DNA-binding proteins from protein sequence based on random forest. Later, Lin *et al.* (2011) developed a new method, iDNA-Prot, for annotating uncharacterized proteins as DNA-binding proteins or non-DNA-binding proteins. Later, in a study by Ma and Wu (2013), authors developed a new approach for identifying DNA-binding proteins using sequence-derived knowledge and support vector machine-sequential minimal optimization (SVM-SMO) algorithm. In a study by Peled *et al.* (2016), authors have utilized biophysical features and random forest to discover DNA and RNA binding proteins. In a recent study by Paz *et al.* (2016) authors have developed a non-homology based approach for prediction of DNA- and RNA-binding proteins. The method utilizes the structure-based features (electrostatic features and general properties of the protein), given the three-dimensional structure of the protein. Wei *et al.* (2017) have

developed a novel approach, Local-DPP, combining local Pse-PSSM (Pseudo Position-Specific Scoring Matrix) with random forest classifier to predict DNA-binding proteins.

Prediction of TF Binding Sites

In the preceding section, we have discussed the identification of DNA-binding site on protein; however, in protein-DNA interaction, DNA also contains specific sites, which are recognized by the protein. These transcription factors (TF), the proteins which bind at specific sites on genomic DNA regulate the process of transcription. The presence of transcription factor on the DNA will attract or impede RNA polymerase, thereby promoting or repressing gene expression, respectively. To gain insight into the overall picture of the functioning genome, it is crucial to determine the genomic positions to which transcription factors bind. Transcription Factor Binding Sites (TFBSs) prediction is one of the well-studied domains in the area of protein-DNA interaction and continues to progress rapidly, as the subject moves from the knowledge of only a few binding events to genome-wide data sets. Various experimental and computational methods have been developed to characterize the binding site of TFs (reviewed in [Xie *et al.*, 2011](#); [Bulyk, 2003](#)). One of the simplest computational approaches, used for the identification of TFBSs is searching for the over-represented nucleotide sequences using motif-detection algorithms. But, since the binding sites of transcription factors are short nucleotide sequences and are tolerant to sequence variations, plus this approach (motif identification) requires a large number of sequences for pattern identification, this approach is severely limited by low accuracy. Sequence-based computational methods for prediction of transcription factor binding sites (TFBSs) are often based on Position Weight Matrices (PWMs), which reflects the degeneracy observed TFBSs among the binding motifs corresponding to a particular transcription factor. PWMs have been utilized by various computational methods to identify the binding site of TFs (reviewed in [Bulyk, 2003](#)). In a recent study [Andrabi *et al.* \(2017\)](#) have shown that the information about the TF binding lies not only at specific binding positions but also extends as far as 200 nt away from the TFBSs.

Another successful approach employed for the prediction of TFBSs is structure-based prediction of TFBSs, which makes use of the available three-dimensional structure of protein-DNA complexes. Structure-based prediction of TFBSs has numerous advantages over sequence-based methods. For example, they can also describe the biophysics of interaction, not possible from a simple sequence-level analysis. However, there are several issues in structure-based prediction of TFBSs. One of the crucial issues is the choice of the scoring function used for estimating the binding energy or affinity of the protein-DNA complex. Two types of scoring functions are usually utilized, physics-based molecular mechanics force fields and the knowledge-based statistical potentials. Molecular mechanics energy function comprises of physicochemical interactions which include van der Waals (VDW) interaction, electrostatic interactions, solvation energy, *etc.* ([Liu and Bradley, 2012](#)). Molecular mechanics energy functions are based on approximations and assume fixed charges. They have been successfully utilized in investigating protein-DNA interactions ([Havranek *et al.*, 2004](#); [Morozov *et al.*, 2005](#); [Siggers and Honig, 2007](#); [Alibés *et al.*, 2010a](#)). Besides the electrostatic and VDW interactions, the physics-based energy function also takes into account the hydrogen bonds, π -cation, and π - π interactions, on the thought that these interactions play a significant role in the stability of the protein-ligand complex. Although the molecular mechanics energy functions can comprehensively illustrate the protein-DNA interactions, they are typically time-consuming. Structure-based methods only consider few snapshots for the prediction of TFBSs, which represents a very small fraction of possible conformations of protein-DNA complexes and because molecular mechanics energy functions are sensitive to conformational alterations, these may result in incorrect identification of TFBSs.

Knowledge-based statistical potentials are deduced from the statistical study of known protein-DNA complexes. They are frequently utilized because they are computationally inexpensive and are comparatively less susceptible to conformational transitions than physics-based molecular mechanics energy functions. Knowledge-based statistical potentials ranges in resolution from atom-based potentials ([Zhang *et al.*, 2005](#); [Donald *et al.*, 2007](#); [Robertson and Varani, 2007](#)) to residue-based potentials ([Mandel-Gutfreund and Margalit, 1998](#); [Aloy *et al.*, 1998](#); [Liu, 2005a,b](#); [Takeda *et al.*, 2013](#)). Recent studies have shown that residue-based statistical potentials also work well in the case of protein-DNA interaction ([Liu, 2005a,b](#); [Takeda *et al.*, 2013](#)). Knowledge-based statistical potentials also differ in terms of their applicability to distance ranges e.g., distance-independent ([Mandel-Gutfreund and Margalit, 1998](#); [Aloy *et al.*, 1998](#)) and distance dependent functions ([Liu, 2005a,b](#); [Zhang *et al.*, 2005](#); [Robertson and Varani, 2007](#); [Takeda *et al.*, 2013](#)). Knowledge-based statistical potentials are limited by two factors. First being the mean force makeup of the statistical potentials. For example, lysine and arginine make specific and nonspecific interactions with DNA in the form of hydrogen bonds and electrostatic interactions. Though knowledge-based statistical potentials could capture the hydrogen bonds implicitly, they are averaged out with the nonspecific interactions. The other originates due to low frequency problem. Recent studies have shown that the interaction between the DNA and aromatic amino acids are abundant; however, very limited knowledge is available about these specific interactions ([Wilson *et al.*, 2014](#); [Wilson and Wetmore, 2015](#)). [Corona and Guo \(2016\)](#), through comparative analysis have shown that the interaction between the DNA bases and amino acid residues Tyr and His are enriched in highly specific DNA-binding proteins and might contribute directly to the TF binding specificity ([Farrel *et al.*, 2016](#)). Some studies have also shown that combining knowledge-based potential with other interactions like hydrogen bond and π interaction improves the accuracy of the TFBSs prediction when compared with atomic-level and residue-level knowledge-based potentials.

Experimental Methods to Investigate Protein-DNA Interactions

In view of various essential roles played by protein-DNA interactions, various experimental methods have evolved over time to elucidate them. Apart from constantly improving technologies to analyze interactions in greater detail and accuracy, some method

Fig. 3 Representative experimental techniques to study protein-DNA interactions: (a) HT-SELEX in which TF is allowed to bind a diverse set of DNA sequences, which are picked up using an antibody and then the sequencing of attached DNA is carried out to infer binding patterns (b) Protein-binding Microarray use the technique of hybridization with pre-selected DNA oligomers. A relatively long sequence can be used to interrogate interactions with many sub-sequences and Bioinformatics approaches help in designing an optimum chip and (c) Chromatin conformation capture (3C) and their variants which can reveal the larger-scale contact maps between different parts of genomic DNA as a result of nucleosome formation.

serve specific purposes and have their own trade-offs. In this section, we will discuss popularly used experimental methods to interrogate protein-DNA interactions. Overall, experimental techniques can be grouped into (a) *In vitro* binding experiments (b) NGS-based methods and (c) other methods. **Fig. 3** gives the schematic representation of the experimental techniques used in investigating protein-DNA interactions. They include protein-binding microarrays, high throughput systematic evolution of ligands by exponential enrichment (HT-SELEX) and Chromosome Conformational Capture (3C). They are briefly reviewed in the following:

***In Vitro* Binding Experiments**

Various *in vitro* techniques popularly used to assay protein-DNA interactions are Protein binding microarray (PBM), High-throughput systematic evolution of ligands by exponential enrichment (HT-SELEX) (Jolma *et al.*, 2010), High-throughput sequencing-fluorescent ligand interaction profiling (HiTS-FLIP), Mechanically induced trapping of molecular interactions (MITOMI), and DIP-chip and DIP-seq (DNA immunoprecipitation followed by microarray (DIP-chip) and DIP followed by high-throughput sequencing (DIP-seq)). All these methods allow high-throughput characterization of DNA-binding proteins. A brief description of these methods is provided below.

Protein binding microarray (PBM)

PBM is a DNA microarray-based technology to ascertain the binding preferences of a transcription factor towards DNA. In this technique, first, the DNA-binding protein is expressed, purified and then is allowed to bind directly to a DNA microarray. The array is then tagged with a fluorescent antibody, which is further utilized to measure the relative amount of protein bound to each probe. The probes in the DNA microarray often consist of large number of possible k-mers. Unique k-mers needed to represent much larger set of subsequences can be designed using *de Bruijn* algorithm (Vassallo and Ralston, 1992).

High-throughput systematic evolution of ligands by exponential enrichment (HT-SELEX)

In this technique, a double-stranded DNA mixture is incubated with a DNA-binding protein immobilized onto a well-plate. The mixture is then washed, and the bound oligonucleotides are retrieved, amplified by PCR and sequenced to identify the TF binding specificities (Ogawa and Biggin, 2012).

High-throughput sequencing–fluorescent ligand interaction profiling (HiTS–FLIP)

It is a high throughput technology to perform DNA sequencing and systematic protein-DNA binding experiment on the flowcell. This allows determining the DNA-binding specificities of a transcription factor (Nutiu *et al.*, 2011).

Mechanically induced trapping of molecular interactions (MITOMI)

It is a high-throughput microfluidic platform widely used to study protein-DNA interactions. In this method, a microfluidic equipment is aligned to a microarray containing programmed DNA, such that the TFs (located onto the surface) can bind to the DNA (Maerkl and Quake, 2007). The equipment allows mechanical trapping of the protein-DNA complexes, thus protecting them from being washed out. The device is then examined to quantify binding of TFs.

DNA immunoprecipitation followed by microarray (DIP–chip) and DIP followed by high-throughput sequencing (DIP–seq)

It is a high throughput method for identifying DNA regions that bind to DNA-binding proteins or transcription factors on a genome-wide scale. In this technique, DNA-binding protein is allowed to bind with genomic DNA, and the bound complexes are then segregated using immunoprecipitation or affinity purification (Gossett and Lieb, 2008; Liu, 2005a,b). The DNA fragments are then purified, amplified, fluorescently labeled and characterized either by hybridization to a DNA microarray or high-throughput sequencing.

NGS-Based Methods

ChIP-Seq and DNase-Seq

With the advancement in the next generation sequencing technologies, ChIP-Seq and DNase-Seq have become the preferred choice of *in vivo* techniques to elucidate the protein-DNA interactions (Meyer and Liu, 2014). Both these technologies estimate the binding occupancy of a DNA-binding protein to the nucleotide sequences.

In ChIP-Seq, the cells are first treated with chemical crosslinks which allows cross linking (covalent binding) of the proteins to each other and then to the DNA. Once the protein-DNA are crosslinked, the chromatin is extracted and DNA is sheared using sonication and the bound complex is isolated utilizing antibodies specific to the protein of interest. The cross-links are then reversed and purified DNA segments are characterized using sequencing.

DNase-seq is a more recent technology developed to obtain the genome-wide protein-DNA binding map. In DNase-seq, protein-DNA complexes are digested with DNase I which preferentially digests the DNA not bound to proteins. The DNA fragments are then extracted, purified and sequenced.

DNase-Seq can be used to interrogate binding sites of large number of TFs in a single experiment. However, the challenge is to assign the identified site to their corresponding TF and powerful Bioinformatics techniques have been developed to address this issue exclusively (Rajagopal *et al.*, 2016).

Conformation capture by 3C, 5C and HiC

The topological structures of the genomic DNA play a significant role in coordinating transcription and other DNA-dependent metabolic processes and thus are of great importance. Chromosome conformation capture (3C) technology developed by Dekker *et al.* (2002) are one of the recent technologies which allow study of chromatin structure in their native cellular environment with high resolution. All 3C and 3C-derived technologies (4C (chromosome conformation capture-on-chip), 5C (chromosome conformation capture carbon copy), HiC, ChIP-loop and ChIA-PET) follow a similar set of protocols to study the 3D organization of the genomic DNA. In 3C methods, first, the genomic DNA is fixed, utilizing fixative agents like formaldehyde (Dekker *et al.*, 2002). Then the chromatin is cut using restriction enzymes and the topologically proximal regions are re-ligated to allow intramolecular crosslinking. The fragments close to each other ligate, thus quantifying the proximity of fragments. The primary difference between 3C methods lies in the fragments of interest. In 3C, also referred as “one-vs-one”, the two specific regions are probed for interaction, which is usually known *a priori*. In 5C, also known as “many-vs-many”, all fragments in a given region are probed for interaction between them. Hi-C (all-vs-all) is an unbiased technique to identify interaction between all potential fragments.

Other Methods

Apart from the techniques discussed above, a plethora of other *in-vitro* and *in-vivo* techniques are also available to interrogate protein-DNA interactions. They include Electrophoretic mobility shift assay (EMSA) (Hellman and Fried, 2007), Yeast one-hybrid assay (Y1H) (Reece-Hoyes and Marian Walhout, 2012), Proximity ligation assay (PLA) (Gustafsdottir *et al.*, 2007), X-ChIP, Fast ChIP, Carrier ChIP, Native-ChIP (N-ChIP), Matrix ChIP, ChIP-Chip (Tong and Falk, 2009), ChIP display (Barski, 2004), other variations of ChIP such as Quick and Quantitative ChIP (Q² ChIP) and MicroChIP, ChIP-loop and ChIA-PET (Li *et al.*, 2014a,b; de Wit and de Laat, 2012), for which the readers are directed to relevant literature.

Computational Methods for Investigating Protein-DNA Interactions

As discussed above, protein-DNA interactions occur in complex and diverse cellular conditions, which are difficult to observe in their native form. Crystal structures do give us a closer look at the atomic level determinants of molecular interactions. However, on the one hand, many protein structures remain unsolved and on the other, it remains unknown if the crystal structures solved *in vitro* represent real cellular context. Some of our data suggests that the three dimensional structures of protein-DNA complexes are cell-type dependent (Andrabi *et al.* Bioarxiv 2015). To address the first of these two issues efforts are made to model protein structures using comparative modeling and predictive models and for the second first principle computations have been attempted. Some of the specific cases have been discussed above. From a technical perspective, the techniques used for modeling DNA-binding proteins are often based on homology modeling and threading (Morozov *et al.*, 2005). A high quality template is an essential requirement for homology modeling and in the absence of a similar protein structure available, data driven approach such as machine learning are a handy choice. For the second issue, *ab initio* physics based techniques can try to emulate the cellular contexts and efforts are going on to bring such techniques as close to the experimental conditions as possible. Homology modeling, Molecular dynamics (MD), Monte Carlo (MC) and machine learning (ML) principles applied to model protein-DNA interactions are not unique to them but are essentially an adaptation from other applications. The technical considerations behind the application of MD, MC and ML techniques have been frequently reviewed and the same can be referred to elsewhere (Tuckerman and Martyna, 2000; Ding *et al.*, 2010; Paquet and Viktor, 2015).

Summary and Conclusions

Protein-DNA interactions are essential components of all biological systems, fundamental to almost all biological processes. Tremendous efforts have been made to understand them employing (a) first principle science such as MD and MC (b) experimental techniques such as ChIP-Seq and HiC and (c) data driven approaches such as ML and statistics. It is not possible to predict DNA-binding sites from sequence with high confidence build homology based models for many novel proteins as well as direct query the nature of genome-wide interactions between TFs and their target DNAs. The studies have so far revealed the role of sequence and structure/shape of the protein and DNA sequences in the recognition process. The current trends are to look at the DNA topology in genome-wide recognition, cell-type specific structures and role for non-binding flanking regions of DNA playing an allosteric role in protein-DNA interactions. Data driven techniques are also going to be a crucial tool to interrogate such large-scale interactions, due to the availability of unprecedented amounts of data emerging from NGS-based techniques under many phenotypic contexts. Even though, no universal recognition code of DNA is yet described, more and more insights are emerging and controlling protein-DNA interactions will become easier with the growing knowhow.

Nomenclature

BN	Bayesian network	MI	Mutual information
CMI	Conditional mutual information	PPI	Protein–protein interactions
DBN	Dynamic Bayesian Network	ODE	Ordinary differential equation
EST	Expressed sequence tags	PTM	Posttranslational modification
GRN	Gene regulatory networks	ROC	Receiver-operating characteristic
KNN	k-nearest neighbors	TF	Transcription factors

Introduction

Genes act as a secret key in governing the entire biological system's function. Genes' cooperation and interactions form a dynamic network that brings about our vivid biodiversity (Cheng *et al.*, 2013). If one gene is regulated, then it affects its targets, which further affect their next targets, causing a domino effect towards the entire cellular environment. A gene regulatory network (GRN) is the collection of molecular regulators (DNA segments, miRNAs, or histones) in a cell that interact with each other directly or indirectly (through their RNA and protein expression products) and with other substances in the cell (Vijesh *et al.*, 2013). By a comprehensive network perspective, we can mine the direct regulations among genes and gain deep insights into various biological processes, which could further facilitate medical related fields such as drug design or drug target discovery.

A GRN is composed of functional linkages between regulators and targets to which their products bind. *Cis*-regulatory element and *trans*-regulatory element are two main regulatory types (Peters, 2008). *Cis*-regulatory elements are present near the structural portion of the gene/protein as the gene they regulate, such as, the photosynthetic protein family, are expressed at the same time in development. Whereas *trans*-regulatory elements can distantly regulate genes from which they were transcribed. Enhancers and multiple *trans*-acting factors are essential for *trans*-control transcription initiations. Regulators contain DNA epigenetic modifications by methylation, miRNA, transcription factors (TFs), and posttranslational modification (PTM) that include histone proteins and other proteins, which are involved in methylation, phosphorylation, acetylation, ubiquitylation, and sumoylation (Fig. 1). Motif is a basic unit of GRN subgraph for these regulators and gene sets regulated with similar functions in networks. Normally, TFs coded by a gene can regulate gene expression by binding to specific motifs. MicroRNAs (miRNAs) regulate gene expression via RNA silencing or posttranscription regulations. Histones can alter the chromatin structure, which further controls the access of TFs and polymerases to genes thus resulting in an expression regulation (Dong and Weng, 2013). Methylation plays a crucial role in regulating gene expression by blocking the promoters that can activate TFs (Phillips, 2008). Large experimental evidence has been gathered to verify biology gene interactions, such as KEGG (see "Relevant Websites section"), Pathway Commons (see "Relevant Websites section"), MetaCyc Metabolic Pathway Database (see "Relevant Websites section"), JASPAR CORE (see "Relevant Websites section"), HistoneDB 2.0 (see "Relevant Websites section") and miRGator v3.0 (see "Relevant Websites section"), GeneHancer (see "Relevant Websites section"), etc. However, this is only the tip of the iceberg in terms of genome knowledge. Huge knowledge mining from genome is still in its infancy. Comprehensive understanding of GRNs is a major challenge in the field of systems biology. Recent advances in high-throughput techniques provide an opportunity to reconstruct regulatory networks, by offering a huge amount of binding data, like ChIP-Seq, miRNA-Seq, ATAC-Seq with expression data RNA-Seq (Cheng *et al.*, 2011). By performing various topological analyses, including its hierarchical organization and motif enrichment, a potential molecular mechanism would be detected. Gene expression microarrays and RNA-Seq provide us another chance to evaluate gene expression dependencies between TFs and its target genes systematically for understanding systematical biological activities (Madan Babu and Teichmann, 2003). Accurate reconstruction of the gene regulatory interactions, forming GRN, is one of the key tasks in systems biology.

The inference of a GRN is often accomplished through the use of gene expression data. So far, there are numerous computational methods and models developed for restoring GRNs in a real cellular environment. However, each of them have their own assumptions and methods, drawing different blueprints that the GRN described. There is still much confusion about the basic meaning of GRN, ways of assessment, and possible biomedical application. Typically, the relationships between genes are directional in nature and they can change over time or in response to external stimulus. Researchers are facing the choice of whether to include extra features such as causality and temporal behaviors when modeling gene networks or not. In this paper, we aim to clarify the meaning and usage conditions for GRNs and also provide a discussion on next steps to bring GRNs closer to clinical and medical application. In the section "Expression Data for Reconstructing GRN," we briefly introduced the expression data composition and two major platforms that generate expression data. In the section "Static Network Models and Inference

Fig. 1 Central dogma and main regulating elements for biological networks at each molecular level.

Methods,” we focus on network inference methods for reconstructing a static GRN. We highlighted methods themselves, the underlying assumptions and advantages/drawbacks by indicating their features and comparing them. For some representative methods we illustrated examples of how they had been applied in real study. In the section “Dynamic Network Models and Inference Methods,” we discussed inferring methods that simulate temporal changes of gene regulations over time in a dynamic GRN. In the section “Network Validation and Assessment of the Network Inference Methods,” we expanded to how to validate the inferred network and brought up several measurements for assessing the performance of different inference methods. In the section “Gene Regulatory Network Inference Development Trend,” we forecast the trend of further development of GRN inference methods, including building comprehensive GRNs by integrating other omics data besides expression data and methods updating trends for resolving current issues during GRN reconstruction.

Expression Data for Reconstructing Gene Regulatory Network

Nowadays, GRNs are mainly reconstructed from gene expression data, which is generated by high-throughput platforms such as microarray and RNA-seq. Microarray technology uses a set of short expressed sequence tags (ESTs) generated from the cDNA library to hybridize target RNAs and then reflect fluorescent intensity, which is used to measure the expression level of certain RNAs. RNA-seq utilizes next generation sequencing (NGS) technology to sequence the cDNA library generated from sample RNAs and then directly generates read (RNA) counts to represent expression level of RNAs. Although their principles and experiments differ, data preprocessing and normalization methods for microarray and RNA-seq vary drastically. Normalized gene expression data generated from either platform have the same form associated with a matrix with M rows of genes under N columns of

conditions (samples). Static network modeling and dynamic network modeling with time series are two typical reconstruction types for GRN. Five representative models related to the two types will be discussed in detail (Fig. 2).

Static Network Models and Inference Methods

Static models reflect interactions among genes at any given time point. These models are often used to describe network topologies and qualitative features of gene relationships (Wang and Huang, 2014).

CoExpression Networks and Relevance Networks

A GRN built with a correlation based method is called a coexpression network (Muhammad *et al.*, 2017). A coexpression network is constructed by calculating pairwise correlations for each gene pairs to form a fully connected graph, and then by applying a threshold scheme to remove edges between genes that are not significantly correlated (Fig. 2(a)). Pearson correlation, Spearman correlation and Euclidean distance are widely used for measuring linear correlations while mutual information (MI) and kernel correlations between two genes (Cheng *et al.*, 2013) are the representative measures for detecting nonlinear correlations. These measures are used to calculate association on a pair of genes to seek if they are coexpression. *P*-value, *Z*-score, clustering coefficient (Elo *et al.*, 2007), and random matrix theory (Luo *et al.*, 2007) are typical threshold schemes for filtering out low content coexpression.

Pearson correlation ρ is the most basic correlation that measures pairwise correlation between two continuous variables.

$$\rho_{X,Y} = \frac{\text{cov}(X, Y)}{\sigma_X \sigma_Y} \quad (1)$$

Here X and Y denote expression levels of two genes. *Cov* is the covariance between gene X , Y and sigma σ indicates the individual standard deviation. Pearson correlation measures the collinearity between two genes with the assumption that both genes' expression level follow an approximately normal distribution, making it unsuitable for measuring genes with nonlinear relationships.

Rank based correlation describes correlations by comparing the rank of the variables (genes) instead of covariance. Take Spearman correlation as an example, which compares the monotonic relationship between two variables (gene). If two genes follow a normal expression pattern and have a clearly linear relationship, then Pearson correlation and Spearman correlation would be very similar. However, if two genes are monotonically correlated, not linearly correlated, only the Spearman correlation could measure the nonlinear relationships. In other words, the Spearman correlation is more general and robust compared to the Pearson correlation, even though information gets lost during the ranking transformation.

Fig. 2 Representative models and steps for reconstructing gene regulatory network. (a) Coexpression network (b) regression based regulatory network (c) Bayesian network (d) differential equation based regulatory network (e) dynamic Bayesian network.

Distance based correlation mainly refers to Euclidean distance, which is the geometric distance between two genes if two genes are assumed to be in the same p -dimensional Euclidean space. Euclidean distance is sensitive to transformations, whereas the other two are normally invariant to linear transformations.

Information theoretic entropy and mutual information concepts provide a new perspective to scale the correlation between variables. Entropy measures the quantity of information within a given system and two variables that contain more entropy tend to be more related. MI measures all the entropy within a system, including marginal entropy from variables and joint entropy between/among variables. A MI $I(X,Y)$ measures a system of two variables (genes) and can be defined as:

$$I(X,Y) = H(X) + H(Y) - H(X,Y) \quad (2)$$

where

$$H(X) = - \sum_{x=1}^m f(x) \log(f(x)) \quad (3)$$

is the marginal entropy and

$$H(X,Y) = - \sum_{x=1, y=1}^{m,n} f(x,y) \log(f(x,y)) \quad (4)$$

is the joint entropy for two continuous variables of gene X and Y .

A gene association network built with MI is called a relevance network (Butte and Kohane, 1999). ARACNe (Margolin *et al.*, 2006) is the most famous and representative algorithm for building a relevance network. ARACNe assumes genes following a normal distribution and performed a Gaussian Kernel estimator (Scott and Sheather, 1985) to estimate marginal distribution $f(x)$ and joint distribution $f(x,y)$ in formula 3 and 4. ARACNe defined its edge-pruning thresholds named data processing inequality (DPI) as: For all available triplets g_i, g_j , and g_k , if g_i interacts with g_k via g_j , then the edges (pairwise MI) among them should follow the following inequality: $I(E_i, E_j) \leq \min(I(E_i, E_k), I(E_k, E_j))$, meaning that the indirect interaction in the system should contain the smallest MI value. Any violated indirect interactions will be pruned.

A GRN based on correlation provides coexpression or cofunctionality from a network scale with no directionality, meaning that if no prior knowledge is provided (e.g., a gene is confirmed to be a transcription factor in a two-gene interaction system), we cannot identify the causations and results of genes in a GRN. MI detects underlying correlations that linear Pearson correlation cannot discover, especially for variables with nonlinear correlation.

Regression Based Approaches

Regression based approaches are a conventional and straightforward method that is widely used in inferring GRNs (Fig. 2(b)). In a regression model, the problem of constructing a GRN is converted to the problem of selecting regulators (e.g., TFs) that have a significant impact towards particular genes. Given an expression matrix with m genes and k conditions. A multiregression model for each gene can be formulated as:

$$y_i = \beta_0 + \beta_1 X_{i1} + \beta_2 X_{i2} + \dots + \beta_k X_{ik} + \varepsilon_i$$

Where: y_i is i th gene of whose regulating relationship towards other genes is to be inferred. β_0 denotes the constant/intercept. X_{ik} indicates the expression values of gene i in condition k . ε_i is the noise/error terms within gene i . For each gene i , a series of beta indicating the contributing towards gene i expression will be predicted. Various feature selection methods can be applied during the inference such as forward, backward, stepwise, ridge, and LASSO. After this step, a p -value cutoff (< 0.05 or less) is usually used to determine whether there is a link between gene i and predictor gene j . If so, the associated beta indicates the weight and the correlation directions.

Regression based approaches not only estimate the underlying associations among genes in a network, but also infer the association intensities. More importantly, the correlations among predictors can easily be incorporated in the formula by adding the correlated predictors' term, making it capable of mimicking real coregulating scenarios in biological networks. However, the model assumes that all the predictors follow a multivariate normal distribution similar to a coexpression network, therefore regression does not infer the directionality of associations.

Bayesian Networks

A Bayesian network (BN) is a probabilistic network model that takes a group of random variables and measures their relationships as a directed acyclic graph (DAG) with all the conditional dependencies among them (Fig. 2(c)). Given a certain network structure G , a BN can be expressed as the following joint probability density function (PDF) p_B (a product of individual marginal PDFs and conditional PDFs):

$$p_B(x_1, \dots, x_n) = \prod_{i=1}^n p(x_i | P_{a_i}^g, \theta_i)$$

Where $P_{a_i}^g$ is the set of parents of node x_i in a graph G , gene node $g \in G$, θ_i is the i th distribution mean, where all gene expression obeys a normal distribution $N(\theta_i, \delta_i)$. All conditional probabilities denote all the edges within the DAG. The product of them clearly indicate the local Markov property of BN: Every node (gene) is conditionally independent of its nondescendants given its parents.

Reconstructing a BN from the given expression data requires two types of inferences: (1) Parameter learning, which infers marginal and conditional distributions of all nodes, and (2) structure learning, which infers the optimal topology that has the biggest overall probability. In parameter learning, the marginal distributions can be either given by prior knowledge or inferred by various methods such as principle of maximum entropy (Clarke, 2007) while conditional distributions are often inferred with approaches such as maximum likelihood estimator or expectation maximization (Friedman *et al.*, 2000). Learning the optimal structure of a BN has been a great challenge for decades. One can always use a brute force approach to go through every possible structure and finally identify the best, which would cost superexponential time complexity to achieve. Thus, most of the existing algorithms for searching the optimal structures are heuristic and progressive. For instance, Monte Carlo Markov chain (MCMC) (Mukherjee and Speed, 2008) methods use approximate sampling approaches. Greedy equivalence search (GES) (Chickering, 2002) proposed a local optimal constraint and performed a stepwise searching scheme. As for the scoring scheme, usually a Bayesian information criterion (BIC) or Akaike's information criterion (AIC) is chosen (Liu, Malone and Yuan, 2012).

Compared to coexpression networks, BNs can clearly point out the directionality of each edge thus revealing a causation relationship among all genes, which is significantly advantageous. Large number experiments have shown that BN can offer a better accuracy and tolerance with noise expression input on small number of genes (Hill *et al.*, 2016). As more variables (genes) are incorporated into the model, the computational time grows superexponentially, which brings up the great challenge of building a whole genomic BN for higher organisms like humans (Hill *et al.*, 2016). Moreover, for one dataset, there might be more than one optimal BN structure that has the equivalent overall probabilities. These models (structures) are called equivalence class (Chickering, 2002), in which each model is probabilistically indistinguishable. Consider two BNs $A \rightarrow B \rightarrow C$ and $C \rightarrow B \rightarrow A$ are probabilistically equivalent since their overall probabilities are $P(A)P(B|A)P(C|B)$ and $P(C)P(B|C)P(A|B)$, which is the same. Causal network (CN) refers to a more strict form of BN, meaning not only conditional dependencies, but also Markov conditions among variables need to be followed in the DAG, which provide a clear causation of one variable over another. Hence, the above BN are not causally equivalent due to different Markov conditions: $A \perp\!\!\!\perp C|B$ (A is independent of C given B) versus $C \perp\!\!\!\perp A|B$ (C is independent of A given B), where in the first network, A causes C , in the second, C causes A . GES algorithm that is mentioned above is a searching algorithm designed for CN models.

Another significant drawback of the BN model lies in its assumption: A DAG doesn't allow the existence of feedback loops, which have been widely proven to exist in biological networks. This can be resolved by dynamic Bayesian network (DBN) (Yu and Liu, 2004; Murphy and Russell, 2002). Additionally, there is no way to observe the type of regulations (activation/inhibition) in a GRN generated with a BN model. Hence, prior knowledge or differential expression analysis is usually incorporated.

Applications

The applications of static models can be found in various fields such as cancer biology and biotechnology (Marbach *et al.*, 2012). Moreover, Chuang *et al.* (2007) constructed a relevance network that uses mutual information to measure protein-protein interactions with protein interaction information from databases and gene expression profiles from breast cancer patients. They were able to identify several important biomarkers that highly correlated to breast cancer metastasis. Zhang *et al.* (2017) utilized linear regression and Cox regression and created a semisupervised learning approach and built a comprehensive drug-disease-gene network for drugs repositioning on ovarian cancer. Yavari *et al.* (2008) clustered genes based on gene ontology (GO) and used a BN to build a regulatory network containing 84 yeast genes based on coclustered information.

Dynamic Network Models and Inference Methods

Dynamic network models capture the dynamic nature of real networks thus yielding quantitative predictions of gene behaviors (Wang and Huang, 2014). If you don't like static models, self-regulations of genes can be reflected in dynamic models.

Dynamic Bayesian Networks

At a given time slice, DBNs show exactly the forms and properties as BNs. However, as an extension of BN, DBNs incorporate time dimensions into the network reconstruction to detect features of dynamic GRNs with time series, including feedback loops and self-regulation that commonly occur in nature and are not able to be simulated by BNs (Fig. 2(e)). A DBN with N genes can be described as:

$$P(X_t|X_{t-1}) = \prod_{i=1}^N P(X_{i,t}|Pa_{Bt}(X_{i,t}))$$

Where $X_{i,t}$ is a given gene i at time slice t and Pa is its parent's set. In a DBN, each node (gene) has duplicates corresponding to the number of time slice t in order to model the cyclic interactions and dynamic behaviors of GRN (Aluru, 2005). Temporal relationships among genes are represented by interconnections between time slices (Chai *et al.*, 2014), which means even though a DBN generates DAGs similar to BN, a DBN could have both interslice connections and intraslice connections. The structural learning and parameter learning of a DBN is similar to a BN. However, to infer the future state, a DBN needs to be converted to hidden Markov models first and then applied with forward or backward algorithms (Murphy and Russell, 2002).

Boolean Network Models

In system biology, a Boolean network refers to a set of genes whose states are binary (activate or inactivate) (D'haeseleer *et al.*, 2000). At a given time slice t , each gene x will only be in one state $S(t)$ where $S(t) = [x_1(t), x_2(t), \dots, x_n(t)]$. States of each gene are determined by one Boolean logic function B , which takes a subset of genes as input and generates the current state for associated genes. Boolean networks use a series of discrete states of the network to represent the complete dynamics of the whole GRN. Current state of the whole network at time slice $t + 1$ is inferred from the network state at time slice t . Hence, to generate a GRN using a Boolean network model, the expression value of genes that are continuous needs to be discretized. The objective of the searching process is to identify a series of logic functions that optimally explain the expression data.

A Boolean network is a simple way to simulate the sophisticated dynamics of GRN. There are several studies that take advantage of Boolean network model and successfully capture some common patterns of regulator genes and the suppressed/activated genes (Shmulevich *et al.*, 2002). However, limitations of the Boolean network model are still obvious: a GRN is a real-time dynamic system and states of genes are more complicated than binary. Hence a Boolean network cannot accurately mimic the real dynamic interactions among genes since gene expression data normally contains a small number of time slices. Moreover, a Boolean network also masks important information during discretization. As gene expression patterns are generally more complex than having only two states, data discretization often leads to information loss.

Constructing GRN Using Ordinary Differential Equations

Unlike Boolean networks or DBNs, GRN modeling by ordinary differential equation uses a series of discrete states to simulate the complete dynamics of GRNs (Fig. 2(d)). Each gene expression variation uses continuous variables to describe the complete concentration change of RNA or protein with generation, degradation, interaction, regulations, and other events. Hence the concentration change of each gene expression is simulated by one or more independent gene variables and their derivatives with an ordinary differential equation (ODE). The following formula is a standard ODE, which denotes the dynamic concentration change of gene x_i expression under the influence from N other genes in the system (Cao *et al.*, 2012).

$$\frac{dx_i}{dt} = f_i(x_1, x_2, \dots, x_n, p, u)$$

Where x_i is the target gene, $x_1, x_2, \dots, x_n$ are n regulator genes that could affect the expression level of x_i . p is the parameter set and u is the external perturbation, all of which are included in a node function f_i .

A differential equation is said to be *linear* if f can be written as a linear combination of the derivatives of x in time t :

$$x^{(t)} = \sum_{i=1}^n p_i(x) x_i^{(t)} + u^{(t)}(x)$$

where $p_i(x)$ and $u(x)$ are continuous functions in x . For a linear system, regression methods can be used to identify the solutions. However, an optimal evolutionary algorithm is normally used to estimate the nonlinear system to obtain the steady-state parameter equation (Kimura *et al.*, 2004).

GRNs based on differential equations have several limitations: using differential equations assumes the concentration of RNA or protein depends solely on the concentration of other genes within the system. The influence from other molecules or mechanisms (e.g., TFs) is not directly taken into account (Vijesh *et al.*, 2013). Moreover, in reality, parameters in differential equations are usually difficult to estimate in an experiment.

Applications

Van Gerven *et al.* (2008) illustrated a DBN based model that is developed to provide prognostics of carcinoid patients. Lähdesmäki *et al.* (2003) presented an algorithm for searching optimal Boolean network models that best mimic yeast regulatory network from 15 time-series expression data. Geva-Zatorsky *et al.* (2006) proposed a differential equation based model for reconstructing the P53 dynamic system, which plays a key role in tumor suppression.

Network Validation and Assessment of the Network Inference Methods

To prove the correctness and fidelity of the inferred GRN, a network validation is essential after the inference. Normally, various microarray experiments *in silico* are conducted to record the expression change after gene perturbations (Yeang *et al.*, 2005), such as knockout, drug treatment, or overexpression. The regulation that exists between two genes can be directly validated by using variation analysis of gene expression and investigate associated biological functions. Moreover, the direction of regulation can be identified (Chen *et al.*, 2015).

Assessing the performance of inference methods is also an important aspect in GRN inference. Generally, for an undirected network, the inferred network model generated from validation data needs to be compared with the associated gold standard to see the consistency of the presence or absence of edges in gold standard. For a directed network, not only consistency of edge presence and absence, but also the consistency of edge directionality needs to be evaluated. True positive (TP), true negative (TN), false positive (FP), and false negative (FN) edge counts should be calculated. And precision (specificity) and recall (sensitivity),

defined as $P = TP/(TP + FP)$ and $R = TP/(TP + FN)$ respectively, can be calculated and used as performance assessments. The higher the P and R values are, the better gold standard network has been restored by the method. To measure the performance of methods under a series of changes, for instance, a parameter change from 0 to 1 with a 0.1 interval, or different inputs with 10 to 100 genes within. A receiver-operating characteristic (ROC) curve (Balakrishnan, 1992) denotes the performance consistency of inference method under different conditions. In a ROC graph, y and x axis indicate true positive rate (TPR) and false positive rate (FPR), which can be further calculated with the respective formula: $TPR = TP/(TP + FN)$, $FPR = FP/(FP + TN)$.

Gold standards that are based on real world data have been systematically built up in both machine learning and system biology fields. ALARM network (Beinlich *et al.*, 1989) is a popular tool that is firstly applied for comparison of reconstructed network in machine learning. DREAM project (Marbach *et al.*, 2009; Prill *et al.*, 2010; Marbach *et al.*, 2010) consists of a series of well-studied regulatory network of prokaryotes, eukaryotes, including *Escherichia coli* (Simmons *et al.*, 2008) and in silico microarray datasets of knock-down, knock-out and their associated transcriptome data are collected and published systematically. Causal molecular networks inference focus specifically on reconstructing the signaling downstream of receptor tyrosine kinases based on phosphoprotein data from cancer cell lines as well as in silico data. Linear regression and pair-wise correlation obtained the best-scoring model for the experimental data and in silico data respectively compared with prior network, Ensemble method, nonlinear regression, ODEs, and BNs. A similar result showed linear correlation outperforms over 30 network inference methods on *E. coli*, *Staphylococcus aureus*, *Saccharomyces cerevisiae*, and in silico microarray data (Marbach *et al.*, 2012). A recent large scale study (Saelens *et al.*, 2018) evaluated 42 methods for detecting coexpression networks on nine genome-wide gene expression datasets, including *E. coli*, *Saccharomyces cerevisiae*, human datasets, and two synthetic datasets. Benchmark results suggested that decomposition methods can detect local coexpression networks while other methods cannot. Topology inference of GRNs from high-throughput omics data is a long-standing open challenge in computational systems biology. Accuracy and speed become a bottleneck for optimum network reconstruction in such big data.

Existing gold standards of biological networks suffer from the following issues: most of the gold standards describe certain biological processes most likely in primitive organisms such as *E. coli* and yeast, which has a significant regulation mechanism compared with humans. Hence they cannot fully reflect the performance of certain methods that are specifically designed for humans. Secondly, many of these gold standards are the product of curated and repetitive studies among different labs, across different time periods, hence under different experiment conditions, which means they represent more general patterns of certain biological processes, which may not necessarily cover some extreme cases. Thus, using these gold standards to benchmark methods developed for extreme cases could result in bias. For instance, a method for inferring GRNs especially for cancer cells will show a biased benchmark result when using gold standards that mimic the GRN in a normal human cell.

Gene Regulatory Network Inference Development Trend

Multi-Omics Data Integration and Hybrid Model

Due the development of genomic, transcriptomic, and proteomic research, numerous novel experiments and computational technologies lead to the explosion of multiomics data curation. For instance, genomic database NCBI (Coordinators, 2016), transcriptomic database ExPASy (Gasteiger *et al.*, 2003), protein database Pfam (Bateman *et al.*, 2002), pathway database KEGG (Ogata *et al.*, 1999), expression data hub GEO (Edgar *et al.*, 2002), and ArrayExpress (Brazma *et al.*, 2003) store thousands of high-throughput datasets across all kinds of diseases. These databases have a considerable overlaps in terms of describing same biological processes or functions. These overlapped data actually measure the same thing however from various different angles. Hence, when building GRNs from expression data, if associated data (e.g., mutation or binding information) can be utilized, then the inference could be more solid, accurate, and comprehensive (Coordinators, 2016). Take Gong *et al.* (2015) as an example; in the article, they integrated data from RNA-seq, histone modification ChIP-seq, transcription factor, and gene perturbation experiments into a DBN model that resembles a temporal control of gene expression patterns during human cardiac differentiation. Moreover, Hore *et al.* (2016) created a comprehensive GRN by incorporating multiomics data into a Bayesian sparse tensor decomposition model. The common features across multiple tissues are discovered from one GRN. Lu *et al.* (2017) combined ChIP-seq data with expression data from RNA-seq to identify transcription factor binding sites and regulatory modules, which could be considered as another novel method of reconstructing a comprehensive GRN. Due to the rapid advancing single-cell techniques, mapping GRNs from single-cell multiomics data could provide opportunities to systematically understand cellular heterogeneity, which can greatly facilitate precision medicine studies (Fiers *et al.*, 2018).

As more types of omics data were incorporated into the model, the number of variables significantly increased, which could cause convergence difficulties of time consuming models such as BN and regression (De Smet and Marchal, 2010). To overcome this issue, novel methods have been developed under two ideas. (1) New models and learning algorithms that contain a higher learning efficiency. Take deep learning as an example; it has been extensively developed and applied during recent years and proven to be successful in many machine learning tasks mainly due to its multiple layers and hierarchical representation. "D-GEX" (Chen *et al.*, 2016), a deep learning method, has been developed for training GRNs from expression data and predicting expression of target genes in cancer. The new model has been proven to have a better outcome compared to linear regression and k-nearest neighbors (KNN) regression (Bentley, 1975). (2) Hybrid models and learning algorithms that incorporate existing approaches together to get a better performance. For instance, Liu *et al.* (2016) developed a hybrid method called a local , which can be summarized as follows: use pair-wise conditional mutual information (CMI) to build a skeleton; then apply a BN model for each

of the genes and their first-order neighbors to determine the direction of regulations; integrate subnetworks into candidate network; and perform CMI again to trim necessary edges so as to obtain comprehensive optimization. Integrating different models to solve the problem might be a feasible way to model expression data with high dimensions. Taken together, these approaches give us new thoughts on using newly developed methods to solve GRN related problems.

GRN Application for Precision Medicine

GRNs can be used to reveal numerous biological functions, which also include cancer initiation and progression. Through a GRN, one may be able to better understand how genes and proteins interact, which further leads to a better understanding of functions of oncogenes and related pathways, offering a better discovery towards drug target identification. A typical application is a GRN approach for precision medicine. Mounika Inavolu *et al.* (2017) developed a novel algorithm that integrates expression profiles with protein–protein interaction (PPI) networks to identify key deregulated subnetworks, which facilitated drug target discovery especially for breast cancer. Precision medicine target-drug selection (PMTDS) is another novel method for detecting individual interaction networks from multiomics data and recommending the optimum targets and associated drugs for precision medicine style (Vasudevaraja *et al.*, 2017).

Biographical Sketch

Enze Liu, Ms. Enze Liu is currently enrolled as a PhD student at the Indiana University School of Informatics and Computing. Before that, he graduated from Royal Institute of Technology, Stockholm, Sweden in 2013 with a master's degree in computational and system biology. He then worked at the Science for Life Laboratory in Stockholm, Sweden and Biomarker Bio-tech corporations in Beijing, China. His research interests mainly lie in the computational biology domain, in cancer biology and personalized medicine.

Lang Li, PhD Dr. Li gained his PhD of Biostatistics from University of Michigan in 2000. He then served Indiana University School of Medicine for 11 years and became the chair of Computational Biology and Bioinformatics and associate director of the Indiana Institute of Personalized Medicine. He recently joined The Ohio State University College of Medicine as the new chair of Department of Biomedical Informatics. Dr. Li's research interests include numerous areas across system biology, drug interaction, and personalized medicine.

Lijun Cheng, PhD Dr. Cheng gained her PhD from Donghua University in China. She started her research career as a postdoctoral fellow at the Indiana University School of Medicine in 2013. Dr. Cheng currently works in the Department of Biomedical Informatics, College of Medicine, Ohio State University as an assistant professor. Her research interests include computational and systems biology mainly in the cancer biology and personalized medicine domains.

MicroRNA and lncRNA Databases and Analysis

Nomenclature

eIncRNA	Enhancer lncRNA	ncRNA	Non-coding RNA
lincRNA	Long intergenic non-coding RNA	PIN	Partially intronic RNA, a kind on lncRNA
lncRNA	Long non-coding RNA	piRNA	Piwi-interacting RNA
miR	miRNA, microRNA	plncRNA	Promoter lncRNAs
miRNA	microRNA	pri-miRNA	miRNA primary transcript
NAT	Natural antisense transcript	TIN	Totally intronic RNA, a kind of lncRNA

Introduction

Over half of the transcription in mammals originates from non-coding regions of the genome, producing noncoding RNA (ncRNA). The function of some non-coding RNA is known, for instance, the ribosomal and tRNA components of the translation system (rRNA and tRNA), small nuclear RNA (snRNA) components of the spliceosome, small nucleolar RNAs (snoRNA) which are mostly involved in modification of RNA bases, and others such as the telomerase guide RNA, tmRNA, which releases stalled ribosomes, and RNaseP RNA, the catalytic component of the tRNA modification enzyme RNaseP. But genome-wide analysis of transcription has revealed that a large fraction of transcripts are from neither known structural classes nor from mRNA. Because RNA synthesis is an energetically expensive process, it is unlikely that miRNAs and lncRNAs, which together make up as much as 65% of transcription ([Kapranov et al., 2007](#)), are accidental noise produced by random read-through from coding gene transcription. Indeed, in the last twenty years, a great deal has been learned about microRNAs (miRNA) and their important role in cellular regulation, but the function of the remaining ncRNAs, loosely referred to as long noncoding RNAs (lncRNA) is, except for a few examples, still obscure. Computational approaches have played an important role in identifying both miRNAs and lncRNAs, and methods are still undergoing rapid development.

MicroRNA

Biological Background

MicroRNAs are typically 22 base long RNAs (lengths can vary from 16–24 bases in different species) that play an important role in gene regulation in eukaryotic organisms, usually acting by targeting the mRNA for degradation or acting as a translation repressor (see ([Catalanotto et al., 2016](#)) for a review of nuclear functions). MicroRNA genes are common in eukaryotic genomes; usually there are thousands of miRNA genes, for instance in human, the ENCODE project reported 11,000 small RNA genes ([The Encode Project Consortium, 2012](#)), and about 2600 mature miRNAs are listed in miRBase ([Griffiths-Jones, 2006](#)). MiRNA genes are located in the introns of protein coding genes (sometimes called miRtrons), in UTRs of coding transcripts, or as completely separate transcripts. The primary transcript (pri-miRNA) is processed to produce a 60–100 base precursor RNA by the splicing process, in the case of intron encoded miRNAs, or by Drosha (DCL1 in plants) in the case of non-intron miRNAs. In either case, the result is a precursor RNA (pre-miRNA), with an extended base-paired hairpin structure. After export from the nucleus, the pre-miRNA is asymmetrically cleaved, near the loop of the hairpin structure, by the Dicer endonuclease to produce a mature miRNA. One strand of the mature miRNA, usually with a strong preference for the strand originating from the 5' end of the pre-miRNA, referred to as the 5p strand, is loaded into the RNA-induced silencing complex, RISC, and the other, the 3p or * strand is degraded. Within the RISC, the miRNA is bound by an Argonaute (Ago) protein, and is used to locate its complementary target mRNA, usually binding in the 3' UTR. The first 2–7 bases of the miRNA, the seed sequence, are particularly important in binding to the target, although extended complementarity or the miRNA and target mRNA is common. The seed region is also of interest because miRNAs with the same seed sequence are generally assigned to the same family. The mRNA is ultimately degraded by one of several pathways once it is bound to RISC. There are many exceptions and differences from the canonical process described above, but the general aspects are highly conserved. In addition to classical miRNA, there are additional classes of regulatory small RNAs including piwi-interacting RNA (piRNA), which interact with piwi proteins, a subtype of Argonaute proteins, and appear to act primarily to repress transcription of transposable elements (for a review see ([Tang, 2010](#))), and small interfering RNAs (siRNA) which are also produced from double stranded precursors by a Dicer-like system. One of the difficulties in predicting miRNAs is that exceptions to almost every aspect of the canonical process, described above, have been found, and while the process is very similar, there are significant differences between plants, animals, and fungi.

From a computational viewpoint, the focus is usually on 1) miR discovery, identifying the miRNA genes or pri-miRNA transcripts from genome or transcriptome sequence and predicting the mature miRNA sequence from the gene/precursor sequence, and 2) predicting the mRNA targets.

miR discovery

Mature miRNAs can be identified experimentally by isolating and sequencing small RNAs, typically 17–28 bases long. The sequences can then be mapped to the reference genome using standard short-read mapping programs such as BWA or Bowtie2 (Friedländer *et al.*, 2012; Hendrix *et al.*, 2010). Mismatches must be allowed since miRNAs may be the target of adenosine to inosine editing (Cai *et al.*, 2009). Pre-miRNAs, which are typically capped and polyadenylated can also be identified in typical RNA-Seq experiments. In this case, the two arms of the miRNA hairpin stem are often detected as separate reads (Kozomara and Griffiths-Jones, 2013). Crosslinking-immunoprecipitation has been used to identify miRNAs bound *in vivo* to Argonaute. This should, in principle, provide much better experimental datasets, but Agarwal *et al.* (2015) suggest that many of these putative sites may be non-functional.

Computational identification of novel miRNA genes in genomic sequence relies on a combination of sequence similarity to known mature miRNAs, typically based on Blast (Altschul *et al.*, 1997) searches, and secondary structure prediction using Unafold (Markham and Zuker, 2008), RNAfold (Mathews *et al.*, 2004), or the Vienna RNA package (Lorenz *et al.*, 2011). MiRNAs are often highly conserved between species, and the conservation of the mature miRNA should be nearly perfect, however due to “arm switching” (Griffiths-Jones *et al.*, 2011), the shift of the mature miRNA from the 5p to 3p side of the precursor hairpin, matching to just mature miRNAs can be problematic, and matching to the pre-miRNA is likely to be more reliable. The second approach to identification of miRNAs lies in detection of the long base-paired hairpin stem of the miRNA. Minimum free energy RNA secondary structure prediction methods are typically used to detect potential hairpin structures (see references, above), usually after pre-screening to restrict the analysis to only 3'UTRs, to identify sequences similar to known miRNA, or to remove protein coding sequences, structural RNAs and transposable elements. Because there are many sequences that are predicted to fold as an acceptable hairpin stem, for instance Bentwich *et al.* (2005) identified about 11 million in the human genome, this basic approach is typically augmented by additional *ad hoc* criteria. These so-called context criteria examine features such as the presence of a base paired region adjacent to the precursor hairpin with a typical 2 base overhang on the 3p arm, require fewer than 4 mismatches between the 5p and 3p arms in the mature miRNA region, absence of loops in the mature miRNA region, constraints on GC-content, minimum predicted folding free energy (Zhang *et al.*, 2006) or alignment score, structural “exposure” of the seed binding region in the mRNA, exclusion of perfect inverted repeats forming the putative pre-miRNA hairpin (possible transposable element) (see, for instance, (Lucas and Budak, 2012; Meyers *et al.*, 2008)), and continuous pairing in the precursor stem. RNA sequencing data is frequently included, requiring that sequences for both the 5p and 3p arms be detected with a minimum number of reads. Most of these features have been determined by inspection from specific sets of predicted or validated miRNAs and their power and generality are often unclear.

miRNA target prediction

There is general consensus that complementarity of the mRNA with the miRNA seed sequence, conservation of the miRNA and mRNA target sequence across species, the predicted stability of the miRNA-mRNA duplexes, presence of multiple sites (abundance), and accessibility of the mRNA target site are among the most important features in predicting mRNA target sites (Peterson, 2014). However many of the same *ad hoc* features listed above may be incorporated. There are literally dozens of predictive methods (for a recent comparison see (Fan and Kurgan, 2015)). The recall (fraction of known miRNA targets identified in known data) and precision (fraction of correctly predicted targets) vary widely, and offer the classic trade-off between high recall-low precision and low recall-low precision.
